

DATASET GENERATION AND NETWORK INTRUSION DETECTION BASED
ON FLOW-LEVEL INFORMATION

AHMED ABDALLA MOHAMEDALI ABDALLA

A thesis submitted in fulfilment of the
requirements for the award of the degree of
Doctor of Philosophy (Electrical Engineering)

Faculty of Electrical Engineering
Universiti Teknologi Malaysia

17th SEPTEMBER 2015

To My Mother for all what she gave to me and for what she is still giving.

I dedicated this humble work to you.

ACKNOWLEDGEMENT

First of all, I would like to express my deepest thanks to ALLAH (SWT), who guided, helped, and supported me.

I wish to send my serious gratefulness and thankfulness to my research supervisors, Associate Professor Dr. Sulaiman Mohd Nor and Dr. Shaikh Nasir bin Shaikh Husin for encouragement, motivation, full support in academic, social, and technical issues. Truly, I have been overwhelmed by their patience, personal kindness, valuable comments, and advices during my study. Without their continuous guidance and help, this thesis would not have been completed.

I have greatly appreciated the opportunity from UTM to pursue my PhD, I thank very much all UTM community including each people at (faculties, library, staff, employees, students and labourers). Special thankfulness to every member of people in FKE, CICT, SPS.

Finally, I would take pleasure in gratitude my mother, father and all the members of my family, friends and relatives for their constant dear one, help and support which motivate me to face the life difficulties.

Ahmed Abdalla

ABSTRACT

The growth of the Internet and networking has made securing networks against attacks a very challenging task. For high-speed networks, flow meta-data inspection can replace conventional Deep Packet Inspection but with the cost of low precision of identifying attacks since the former deals with an aggregated version of the traffic. The first part of this research addresses the problem of the lack in benchmarking datasets for developing new Network Intrusion Detection Systems (NIDSs) or comparing existing NIDSs. The aim in the second part is to design a near real-time NIDS without degrading the detection accuracy when compared to conventional misuse packet-based approaches. To achieve the first objective, a NIDS dataset creation framework had been developed. Based on that framework, a flow-level NIDS dataset had been created. The traces were collected from campus main routers in NetFlow format while malicious traffic of different attack scenarios was generated by Nmap and BoNesi tools. In the second part a flow-based software-based system were developed to detect and identify network volume-level attacks in near real-time. Attack detection is based on statistical time-aggregated features of the exported NetFlow version of the traffic to detect several scan and Denial-of-Service (DoS) attacks. A validation for the designed system is done using Defense Advanced Research Projects Agency (DARPA) datasets. The timeline performance outperformed all relevant software-based systems and suited for up to one gigabit per second links with an average detection delay of less than one minute. The proposed method achieved 95% True Positive Rate (TPR) and almost zero False Positive Rate (FPR). Compared to relevant methods when operated in the same conditions, the proposed method improved the TPR by 4% and improved FPR by 1%. In addition, the capability of flow-based approach in detecting packet-level attacks was experimentally demonstrated. The results against Snort were benchmarked and 75% TPR and almost zero FPR were achieved.

ABSTRAK

Pertumbuhan Internet dan rangkaian telah menjadikan keselamatan rangkaian terhadap serangan satu tugas yang sangat mencabar. Untuk rangkaian kelajuan tinggi, penelitian meta-data boleh menggantikan penelitian tahap paket konvensional tetapi dengan kos ketepatan rendah semasa mengenalpasti serangan memandangkan tahap-aliran berkait dengan agregasi trafik. Bahagian pertama kajian ini bertujuan menyumbang dalam menyelesaikan masalah keperluan set data penandaan aras yang piawai untuk membangun Sistem Pengesanan Penceroboh Rangkaian (NIDS) baru atau membanding dengan yang sedia ada. Tujuan di bahagian kedua adalah untuk merekabentuk NIDS masa nyata berhampiran tanpa merendahkan ketepatan pengesanan apabila dibandingkan dengan pendekatan konvensional penyalahgunaan berasaskan paket. Bagi mencapai objektif pertama satu rangka kerja bagi mewujudkan dataset NIDS telah dibangunkan. Berdasarkan rangka kerja tersebut dataset tahap-aliran NIDS telah dibangunkan. Surih dikutip dari penghala utama kampus dalam format *NetFlow* manakala trafik hasad dari senario serangan berbeza telah dihasilkan oleh peralatan *Nmap* dan *BoNesi*. Dalam bahagian kedua, satu sistem berasaskan perisian tahap-aliran telah dibangunkan bagi mengesan dan mengenalpasti serangan rangkaian tahap-jumlah dalam masa nyata berhampiran. Pengesanan serangan adalah berdasarkan kepada ciri-ciri statistik masa terkumpul trafik *NetFlow* versi yang dieksport bagi mengesan beberapa imbasan dan serangan Penafian Perkhidmatan (DoS). Pengesanan sistem yang direkabentuk dibuat menggunakan set data Agensi Projek Penyelidikan Termaju Pertahanan (DARPA). Prestasi had masa sistem telah mengatasi sistem lain berasaskan perisian dan hanya sesuai sehingga kelajuan satu gigabit sesaat dengan purata lengah kurang dari satu minit. Kaedah ini berjaya mencapai 95% Kadar Positif Benar (TPR) dan hampir sifar Kadar Positif Palsu (FPR). Berbanding dengan kaedah berkaitan apabila beroperasi dalam keadaan yang sama, kaedah ini telah memperbaiki TPR sebanyak 4% dan memperbaiki FPR sebanyak 1%. Sebagai tambahan, kemampuan kebolehan pendekatan berasaskan aliran di dalam mengesan serangan tahap paket telah dapat ditunjukkan secara eksperimen. Keputusan berbanding dengan *Snort* telah ditanda aras dan telah mendapat 75% TPR dan hampir sifar FPR.

CHAPTER 1

INTRODUCTION

1.1 Overview and Motivation

The global growth of the Internet and networking has made securing networks and information one of the most challenging tasks in the field of network communication. Today, intrusion attacks are generating significant worldwide epidemic to network security environment and bad impact involving financial loss. Intruders have the capability to infect thousands of hosts and networks within few minutes before human action takes place.

Studies on the field by Dell™ SonicWALL™ Threat Research Team demonstrated that network attacks are increasing exponentially every year. For example, over 20.1 million unique malware samples were collected in 2013, compared to 16 million in 2012 ([DellSonicWALL, 2013](#)). In the year 2013 more than 1.06 trillion intrusion related incidents had been detected and prevented and more than 1.78 billion malwares downloads had been blocked. According to the same report, there were approximately 4,429 new vulnerabilities reported from [Common Vulnerabilities and Exposures \(CVE\)](#) and 3,644 were related with network attacks in 2013 ([DellSonicWALL, 2013](#)). Even a small security breach on commercial dealings such as online e-payment and money transactions may cause huge unrecoverable losses to companies and individuals. Successful attacks to hijack network-based sensitive services in hospitals or airports may lead to disastrous results.

In response to those increasing cyber-attacks, the cost of securing networks information is also increasing. According to the industry survey on cyber security conducted by New York State Department of Financial Services (Andrew M. Cuomo, 2014), 77% of institutions involved in the survey experienced an increase in their total information security budget in the past three years. Almost no institutions reported a reduction in spending in the past three years.

In order to cope with the enormous increasing security threads that face network communication, various third party techniques or middle-boxes techniques have evolved such as firewalls, Network Intrusion Detection Systems (NIDSs). Network Intrusion Detection Systems (NIDS) proved to be an efficient technique that can process large volume of networks traffic and detect intrusions in their early stages in order to limit their catastrophic damages.

Intrusion can be defined as any activity that violates confidentiality, authority, integrity or availability of information system (Lazarevic et al., 2005). Although in the field of information security, intrusion and attack are used interchangeably, there is a little difference between the two terms. An attack is an intrusion attempt, and an intrusion results from an attack that has been (at least partially) successful (Barrus and Rowe, 1998). Intrusion Detection is defined by The National Institute of Standards and Technology (Bace and Mell, 2001) as “the process of monitoring the events occurring in a computer or network and analyzing them for signs of intrusions”. An Intrusion Detection System (IDS) can be defined as a combination of software or/and hardware components that monitors computer and network systems and raises an alarm when intrusion happens (Lazarevic et al., 2005).

There are two main categories of IDSs; host-based IDSs (HIDS) which are designed for single host, and network-based IDSs (NIDS) which monitor the whole traffic of a network. Generally, the concepts of IDS is more related to NIDS than HIDS since the latter can be considered as an ordinary antivirus system limited to one host whilst the prior is an entity that can monitor a whole enterprise network or even an ISP network.

1.2 Background

1.2.1. A Simple NIDS Architecture

In general, the components which make up any NIDS can be viewed as shown in Figure 1.1 (Lazarevic et al., 2005).

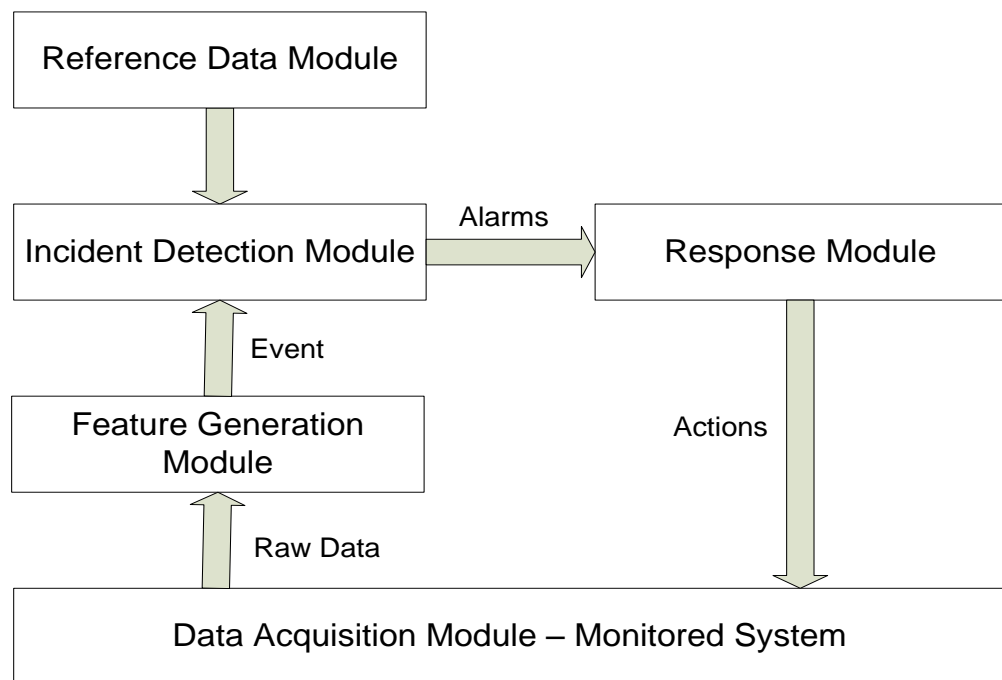

Figure 1.1 Simple architecture of NIDS (Lazarevic et al., 2005)

The purpose of each module is as follows:

- i. Data Acquisition Module: Responsible for collecting network traffic data.
- ii. Feature Generation Module: Responsible for extracting a set of selected traffic features (packet header features, payload features, flow features)
- iii. Incident Detection Module: Responsible for identifying intrusion and generating alarms by comparing the data generated from the feature generation module with that of the reference module. Generally there are two methods of this detection; misuse-based detection and anomaly-based detection.
- iv. Response Module: Once an alert is received, this module is responsible for initiating actions in response to a possible intrusion.

- v. Reference Data Module: This module contains the reference data that is to be used by the incident detector to compare with. If the detection method is misuse-based then this data would be based on the description of all known intrusion (intrusion database), and if the detection method is anomaly-based then it would be based on description of normal attack free network operation (network profile).

1.2.2. IDS Taxonomy

Several taxonomies had been proposed for categorizing NIDS, but the most common and acceptable one is that one used by Axelsson (2000) and Debar et al. (1999). This classification categorizes IDSs according to the following aspects:

- i. Information source: NIDS can be packet-level based or flow-level. Packet-level NIDS can be further divided to packet header-based or payload-based.
- ii. Analysis Strategy (Detection Method): This categorization distinguishes NIDS according to the nature of reference data used for identifying intrusions which is either misuse-based or anomaly-based.
- iii. Architecture (Locus of Detection): NIDS can be centralized when it is placed in single position or distributed when there are several points for monitoring.
- iv. Response to intrusion: NIDS can be either passive when it is just to raise an alarm on detecting intrusion or active when a further action is to be done in response to that intrusion.
- v. Time Aspects: NIDS can work in real-time and detect intrusions while they are taking place or by batch (non real-time).

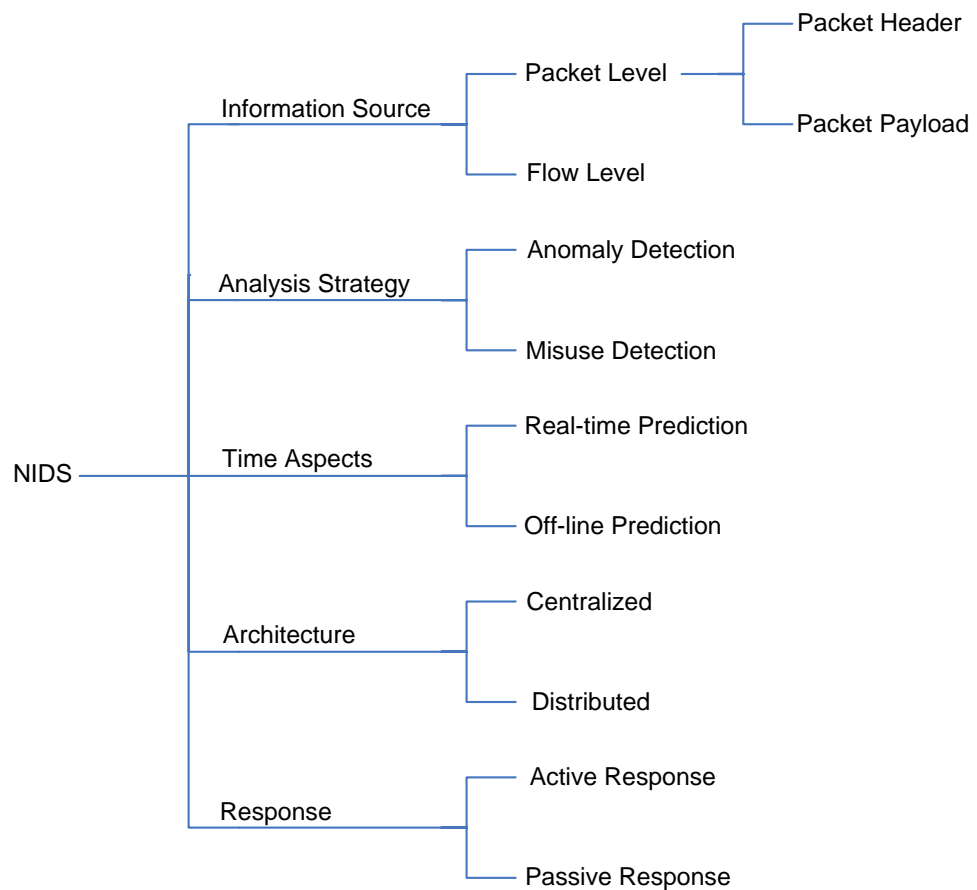

Figure 1.2 NIDS classification aspects

1.2.3. NIDS Required Characteristics

The required NIDS characteristics had been specified by many researchers (Lazarevic et al., 2005, Catania and Garino, 2012). These characteristics are required from NIDS to achieve security goals. We can summarize these characteristics as follows:

- i. High Detection Performance: Detection of all attacks without false alarms
- ii. Low Processing time: Attack is to be detected as soon as possible
- iii. Adaptability: NIDS should be able to readapt itself to deal with novel attacks and changing environments
- iv. Fault tolerance: robustness, resistance to attacks, quick recovery from successful attacks
- v. Minimum Resource consumption: storage resources and processing capabilities needed.

1.3 Problem Statement

As stated in the previous section, NIDS have a wide range of approaches to be categorized accordingly (Figure 1.2). However, there are two main different approaches now for NIDS. The conventional and most common implemented approach nowadays is the misuse-based NIDS with deep packet inspection (DPI), which tries to detect attacks based on previously prepared database of all known intrusion signatures. This approach proved to be efficient and accurate for detecting known intrusions but cannot detect novel and new attacks or even new variants of known attacks. Another drawback of misuse-based NIDS is that it uses DPI. This approach of auditing data by inspection inspects every incoming packet in the traffic. Hence, it cannot cope with high speed networks. Besides, it seems that researches on misuse-based NIDS have reached a saturation point making it harder to make further enhancements.

The other approach is the anomaly-based NIDS, which is based on detection of deviations of a normal attack-free model of the protected network and flagging these deviations as intrusions. This approach can detect known and novel attacks as well. Although this latter approach seems promising and in spite of lot of researches on it, it is still immature and suffers from serious problems that makes it impractical for real life situations. The major problem of anomaly-based NIDS is that it suffers from high false alarm rates. This problem arises from the difficulty of specifying normal and abnormal thresholds for any network and which itself can be considered as a second problem. A third problem of that approach is the limited capacity and precision of identifying an attack when an alarm is raised. This problem is a consequence of anomaly-based detection nature which reacts with any network event as either normal or abnormal (anomaly) and nothing else. If we consider the fact that there are lots of network anomalies that are neither attacks nor intrusions, then definitely there would be a high rate of false alarms.

With respect to the information inspected (audit data), some NIDS inspect the complete traffic (Deep Packet Inspection) for known attack signatures (byte patterns) whilst others consider data from packets headers for attacks that violates network

protocols rules. Meanwhile, other NIDSs depend on extensive summaries and aggregations of traffic flow (flow-level) for intrusion that attack network resources. Each of these levels of audit data inspection concentrates on particular category of intrusive attacks and, therefore, is strong on some parts but may be poor on other parts. Since flow-level NIDS deals with aggregations and summarization of traffic, it can inspect high speed traffic in a near real-time mode. However, it suffers from low precision of specifying attacks in the traffic. This problem is a result of the absence of the actual data in the detection and the use of metadata instead. The whole flow is to be flagged when an attack is detected. The exact malicious packet(s) cannot be specified nor the exact attack time nor any other further information that can help to describe the attack.

Any NIDS needs to go through a knowledge acquisition process to build a reference model in the system before the actual detection process can take place. To build this reference model, the system must be supplied with previously known categorized dataset so that the system would acquire the necessary information to detect attacks and differentiate between malicious and non-malicious incidents in network traffic. Unfortunately, creation of optimum NIDS dataset that would acquire all required characteristics is very hard and costly. In addition, some of these required characteristics seem to be contradicting with each other. Hence, combining these characteristics in a dataset is almost impossible. There are a number of challenges and difficulties in creating ideal datasets. For all that, researchers on NIDS generally suffer from a lack of standard datasets for developing and training new systems. The problem is even severe when looking for benchmarking common public datasets for validating, evaluating and comparing between existing systems and methods.

Most NIDS in the research community today have achieved a very high degree of accuracy in detecting intrusions. However, the majority of these systems face difficulties when they are to be deployed and implemented in real world. With the growing connection speed by the establishment of end users broadband Internet, the data volumes in the backbone networks has increased steadily. Monitoring of links that may reach few gigabits per second capacities by NIDS may require more

computational resources than that available on commodity computer hardware. This problem of resource demand is commonly solved by engineering dedicated hardware platforms such as on Field-Programmable Gate Array (FPGA) that can process detection tasks more efficiently. However, specially crafted hardware comes at a significant higher cost and may not be worthwhile in every situation.

Our research problem is divided into two main parts. The first part aims to deal with the problem of the lack in standard benchmarking datasets for developing and training new systems or comparing existing ones. The second part tries to find software-based solutions for flow-level NIDS to achieve accurate near real-time detection. As a part from the second problem, the research tries to answer some questions concerning the capability and efficiency of flow-level attributes to detect network traffic attacks in spite of the absence of actual monitored data, and to find its efficiency in terms of accuracy and timeline performance.

1.4 Research Objectives

The objectives of this research can be summarized as follows:

1. **To create a labeled flow-level dataset for anomaly-based NIDS using a general framework that would be available publicly.**

A labeled flow-level NIDS dataset is a set of flow records with each flow record labeled as either benign or malicious. A flow record is the set of attributes that abstracts and summarizes all the information which concerns a single session between two communicating entities in a network. The dataset is to satisfy a set of conditions and guidelines in order to acquire validity for anomaly detection.

2. **To design an effective near real-time anomaly-based NIDS to detect brute-force attacks based only on software solutions.**

Effective here means the proposed solution will not degrade the detection accuracy and will not increase the false alarm rate compared to existing conventional DPI or relevant flow-based methods. The system is supposed to detect network intrusion attacks when they are taking place not more than few minutes after the attack has commence. Detection scope of the system consists of all attacks that consume significant network bandwidth in any phase of the attack. The detection system is a set of developed software that does not need special hardware platform to run on and meant to be placed in the ingress/egress point of Universiti Teknologi Malaysia (UTM) campus network. Hence, it has to cope with high speed traffic of possibility to few hundreds megabit per second.

3. To investigate the efficiency of flow-level traffic inspection to detect packet content-based attacks.

The capability, accuracy and timeline performance of flow-level features to detect attack contained in payload packets will be investigated and evaluated.

1.5 Research Scope

This research focuses on developing a system that can monitor the traffic of server farm in UTM campus network in real-time and setting alarm when observing intrusive activities. Hence, the research deals with traffic bandwidth not exceeding one gigabit per second, as this is a little higher than the core bandwidth of UTM campus backbone.

All proposed solutions are software-based and are to be run within general purpose computer machines that are commercially available in the market. No special hardware platform such as FPGA would be considered.

Although the study includes misuse detection approach, it will limit inspection level to flow features and will not consider any of payload inspection or

pattern signature as information source for intrusion detection. Inspection of flow-level data is limited to network and transport layers. Hence, attacks and techniques in lower layers (physical layers) and upper layers (application layers) will not be considered.

All proposed solutions and systems are passive with respect to the detected intrusions. Their role is solely to flag an alarm when any intrusive activity is detected with no further action to be performed.

The study is about Network IDS. Hence, all techniques reviewed, studied or analyzed will depend only on network traffic data (packets and flow data). Host IDS is out of scope of this study. Intrusions would be considered an attack when it uses network resources to scan, propagate, or penetrate network information resources. Intrusions affect information sources through other means (e.g. physical access) will not be considered as network attack.

1.6 Significance of the Research

The most significant contribution of this study is the development of a general framework to create NIDS datasets. That framework would be available publicly for research community. This would help other researchers to develop their own systems and methods and ease the comparison and validations for these new systems and methods.

Another outcome of the study is a cost effective solution to the problem of real-time traffic monitoring in any enterprise networks with up to one gigabit per second bandwidth. It provides a user-friendly NIDS that make the security task easier and provide an early alarm security system for the monitored network through developing an efficient NIDS as a step to replace other costly commercial software products that are currently being used.

1.7 Thesis Organization

The rest of this thesis is organized as follows. In Chapter 2, an overview on the evolution of NIDS and its state-of-the-art that highlights gaps and defines future trends is given. This is followed by an overview on network traffic generating, capturing and processing tools and the significant theories and methods used in NIDS in general. A deep flow-level NIDS literature review is done followed by another review on NIDS datasets.

Chapter 3 shows the overall research methodology, explains and discusses general dataset creation framework, the framework of flow-level detection of brute-force attacks, explains the framework of flow-level detection of packet-level attacks. It also discusses with details all experimental setups, dataset creation steps, validation methods and rational constructions behind the selected methodology.

Chapter 4 presents the implementation details of creating brute-force attacked dataset from captured traffic traces, statistics and various distributions of the created dataset and discusses the corresponding results.

Chapter 5 presents the implementation details of designing flow-level NIDS to detect brute-force attacks and all partial and final results concerning evaluation of accuracy and performance and validation of the detection method and discusses results.

Chapter 6 presents the implementation details of investigating the efficiency of flow-level data to detect packet-level attacks and a discussion to justify the results.

Chapter 7 concludes all the study and states the degree of objective fulfillment, highlights research contributions and makes suggestion for future work.
