ACKNOWLEDGEMENT

I would like to take this opportunity to express my sincere appreciation to all those people and organizations who contributed to this study. My first thanks and appreciations goes to both my supervisor, Associate Professor Dr.Wan Aizan Bt Wan Abdul Rahman and Professor Dr. Ahmad Fauzi Bin Ismail, for their support, guidance and willingness to teach and share their experience throughout this research project.

I am grateful to University Teknologi Malaysia for funding me generous financial support UTM-PTP fellowship award, that the enabling this work to be successfully. I would also like to thank the following people for their assistance, Mr Ng Be Cheer, who always give me a lot of suggestions and explanations, Mr Sohaimi Bin Abdullah, who provided technical advices, Mr Ayob Bin Abu, who run the Scanning Electron Microscopy, Mr Roslan, who run the Attenuated Total Reflection Fourier Transform Infrared Spectroscopy machine and Mrs. Rosmawati, who always helps me throughout this study.

My sincere to all my colleagues at “Membrane Research Unit” *Miss Suhaina, Miss Suhana, Miss Hasrinah, Miss Noraida, Miss Nawal, Miss Sunarti, Mr Syed Mohd Saufi, Mr Hafiz, Mr Idham, Mr Fazli* , with whom I enjoyed many hours of their company and others who have provided assistance at various occasion. Thanks for given me substantial moral support to finish the study. Above all, I thank Allah the Almighty for His grace, mercy and guidance throughout my life.

ABSTRACT

The objective of this study is to develop high performance and defect-free asymmetric polyethersulfone (PES) membranes for O₂/N₂ separation by manipulation of phase inversion process and rheological factors, including different type of nonsolvent additives, polymer concentration, shear rate and evaporation time. Asymmetric flat sheet membranes were fabricated using a pneumatically-controlled casting machine through a simple dry/wet phase inversion process. 1-methyl-2-pyrrolidone (NMP) was employed as a solvent while distilled water (H₂O) and ethanol (EtOH) were used as nonsolvent additives (NSA). For the first stage of this study, three types of casting solution using H₂O as NSA and three types of casting solution using EtOH as NSA had been formulated through titration method. On the next stage, the membranes were fabricated at constant shear rate and evaporation time which is 233.37 s⁻¹ and 12s respectively. Consequently, from the pure gas permeation test results, it was found that the optimum weight percent of PES in casting solution were 32.62 wt% and 26.71 wt % when H₂O and EtOH were used as NSA, respectively. Both of the casting solutions were chosen for optimizing the effect of shear rate and evaporation time. Finally, the membranes were fabricated at five different shear rates ranging from 111.67s⁻¹ to 744.44s⁻¹ and at six evaporation times ranging from 8s to 20s. The results showed that as the shear rate increased, the selectivity and pressure-normalized flux increased until critical shear rate was reached. The best shear rate was found at 233.33s⁻¹ and 148.89s⁻¹ when H₂O and EtOH were used as NSA, respectively. The rheologically induced molecular orientation in asymmetric membranes was observed by analyzing the wave length showed by Attenuated Total Reflection Fourier Transform Infrared Spectroscopy (FTIR-ATR). On the other hand, as evaporation time was increased, the selectivity would increase but the pressure-normalized flux would decrease. The best evaporation time was found at 12s for both casting solution. Thus, the different NSA showed different influence on gas separation characteristics and structures of the produced membranes. The newly developed PES membranes with new casting solution formulation that used H₂O as the NSA, exhibited O₂/N₂ selectivity and pressure-normalized flux at about 7.95 and 9.71 GPU for O₂ respectively. The average skin layer thickness of these membranes was approximately 538.32Å. As for the membranes using EtOH as NSA, the O₂/N₂ selectivity and pressure-normalized flux were 5.01 and 14.07 GPU for O₂, respectively. The calculated average skin layer thickness was about 369.77Å. Therefore, the PES membranes prepared from NMP/H₂O solvent systems proved to provide the best separation characteristics compared to those membranes produced from NMP/ EtOH solvent system. As a conclusion, the combination of phase inversion process and rheological factors had successfully developed high performance, defect-free and hyperthin-skinned layer PES asymmetric membranes for O₂/N₂ separation.

ABSTRAK

Objektif penyelidikan ini adalah untuk menghasilkan membran asimetrik polyethersulfona (PES) berprestasi tinggi dan bebas kecacatan bagi proses permisahan O_2/N_2 dengan pengolahan proses fasa balikan dan faktor reologi, yang merangkumi bahan tambah bukan pelarut yang berbeza, kepekatan polimer, kadar ricih dan masa penyejatan. Membran asimetrik kepingan rata dihasilkan menggunakan mesin penuangan bersistem kawalan-pneumatik melalui proses fasa balikan kering/ basah. 1-methyl-2-pyrrolidona (NMP) digunakan sebagai pelarut, manakala air suling (H_2O) dan ethanol (EtOH) digunakan sebagai bahan tambah bukan pelarut (NSA). Pada peringkat pertama kajian, tiga jenis larutan tuangan menggunakan H_2O sebagai NSA dan tiga jenis larutan tuangan menggunakan EtOH sebagai NSA disediakan melalui kaedah penitratan. Peringkat berikutnya, membran disediakan pada kadar ricih dan masa penyejatan malar iaitu pada $233.37 s^{-1}$ dan 12s. Seterusnya, daripada keputusan ujian kebolehtelapan gas tulen, didapati peratus berat PES yang optimum dalam larutan tuangan adalah 32.62 wt% dan 26.71 wt % PES apabila H_2O dan EtOH digunakan sebagai NSA. Kedua-dua larutan tuangan tersebut kemudiannya dipilih untuk mengoptimumkan kesan kadar ricih dan masa penyejatan. Akhirnya, membran dihasilkan pada lima kadar ricih yang berbeza dalam julat $111.67s^{-1}$ hingga $744.44s^{-1}$ dan pada enam masa penyejatan yang berbeza iaitu dalam julat 8s hingga 20s. Keputusan menunjukkan bahawa apabila meningkatnya kadar ricih, kememilihan dan fluks tekanan-ternormal akan meningkat sehingga kadar ricih kritikal dicapai. Kadar ricih yang terbaik adalah pada $233.33s^{-1}$ and $148.89s^{-1}$ apabila H_2O dan EtOH digunakan sebagai NSA. Reologi penghalaan molekul teraruh pada membran asimetik boleh dianalisa dengan panjang gelombang yang ditunjukkan oleh Pemantulan Jumlah Terkecil-Spektroskopi Infra-Merah Penukaran Fourier (FTIR-ATR). Selain dari itu, dengan meningkatnya masa penyejatan, kememilihan membran turut meningkat tetapi fluks tekanan-ternormal menurun. Masa penyejatan yang terbaik diperolehi pada 12s bagi kedua-dua larutan tuangan. Oleh itu, NSA yang berbeza menunjukkan pengaruh yang berbeza kepada ciri-ciri pemisahan gas dan struktur membran yang terhasil. Penghasilan PES membran dengan formulasi larutan tuangan terbaru menggunakan H_2O sebagai NSA menunjukkan kememilihan O_2/N_2 dan fluks tekanan-ternormal untuk O_2 adalah 7.95 dan 9.71 GPU. Purata ketebalan lapisan kulit membran ini dianggarkan 538.32\AA . Untuk membran yang menggunakan EtOH sebagai NSA, kememilihan O_2/N_2 dan fluks tekanan-ternormal untuk O_2 adalah 5.01 dan 14.07 GPU. Purata ketebalan lapisan kulit yang dikira adalah 369.77\AA . Oleh itu, PES membran yang disediakan dari sistem pelarut NMP/ H_2O telah terbukti menunjukkan ciri-ciri pemisahan yang lebih baik berbanding dengan PES membran yang disediakan dari sistem pelarut NMP/EtOH. Sebagai kesimpulan, penggabungan proses fasa balikan dan faktor reologi telah berjaya menghasilkan PES membran yang bebas kecacatan dan berkulit hiper nipis bagi permisahan O_2/N_2 .

CHAPTER I

INTRODUCTION

1.1 Membrane Formation for Gas Separation

Membranes have gained an important place in separation technology and are used in a broad range of applications. As a general definition, membrane is regarded as a selective barrier between two phases (Mark *et al.*, 1985; Sirkar and Winston Ho, 1992; Ismail, 1997; Pandey and Chauhan, 2001). Membrane should always be associated with its application according to this definition. These applications can range from desalination, dialysis, filtration to gas separation (Kools, 1998). Membranes are normally classified according to the pore size or the size of the materials they are used to separate.

According to Koros and Fleming (1993), there are three areas which were considered critical issues controlling successful membrane-based gas separation. These areas are material selection, membrane formation and module and system configuration. Material selection is important because it will determine the maximum achievable selectivity for the particular membrane. The membrane formation process is responsible for the production of an optimized skin layer to ensure greater enrichment and higher productivity. Finally, the efficiency of the membrane system is highly dependent on the membrane module design and system configuration. The membrane formation and material selection are the aspects that were considered in this study.

The majority of membrane materials for gas separation are polymeric, however there is a steady growth in the application of inorganic material like ceramic, metal, carbon and glass membranes (Ismail, 1997). Membrane gas separation by polymer membrane is a proven technology that has found a wide range of application. For membrane formation, membrane can be prepared by phase inversion technique and can be further divided into four different techniques namely thermal precipitation, air casting of casting solution, precipitation from the vapor phase and immersion precipitation. Among these techniques, immersion precipitation is widely used to produce commercial gas separation membranes and others membrane-based separation available at present (Van de Witte *et al.*, 1996). This process had been used to form ultrathin-skinned and defect-free asymmetric membranes from variety of glassy polymer (Pesek and Koros, 1993; Peinemann and Pinnau, 1988; Pinnau *et al.*, 1990). For membrane preparation, the polymer solution generally consists of either a binary mixture of polymer and solvent or a ternary mixture of polymers, solvents, and nonsolvents (Pesek and Koros, 1993). The equilibrium thermodynamic data on ternary system (polymer/solvent/nonsolvent additive) can be determined by using turbidimetric titration method. Polymer precipitation curves were obtained by a simple titration to get the exact amount of nonsolvent additive value (Lau *et al.*, 1991).

According to previous researchers, different type of nonsolvent additive (Wang *et al.*, 1997; Lai, 1996; Wang *et al.*, 2000), shear rate (Sharpe *et al.*, 1999; Ismail *et al.*, 1997; Ismail and Yean, 2002; Ismail and Lai, 2003c, Niwa *et al.*, 2004), polymer concentration (Wood *et al.*, 1993; Lai, 2002; Ismail and Lai, 2003c) and evaporation time (Yamasaki *et al.*, 1999; Lai, 2002, Ismail and Lai, 2003c) are most widely studied since these parameters significantly influence membrane structure and performance.

Nonsolvent additives have influence the casting solution properties, gas separation characteristics and structures of the resulting membranes, therefore plays an important role in membranes making. The role of a nonsolvent additive is in controlling the membrane morphology and it also used to elevate the porosity of asymmetric membrane. Other attempts to explain the additive effect on membrane

formation have also been made by Kim and Lee. They elucidated that additive could be known as pore former on the structure formation of membranes (Kim and Lee, 1998). The addition of a suitable nonsolvent additive into the membrane casting solution accelerates the coagulation process from solution to gel when the casting solution was immersed in coagulant. As a result, membranes with thinner skin layer and more uniform structure were obtained (Wang *et al.*, 1995a). The addition of a nonsolvent additive in the polymer solution was to bring the solution composition closer to the point of phase separation (Kapantaidakis and Koops, 2002) in order to speed up precipitation of phase-separated structures and reduced relaxation effects on molecular orientation (Chung *et al.*, 2000b; Ismail and Lai, 2003a).

From different perspective, Ismail and co-worker and Shilton and co-worker had identified that rheological factor such as shear rate is an important parameter during membrane fabrication process. Increased shear rate during spinning increases molecular orientation and, in turn, enhance selectivity (Shilton *et al.*, 1997; Ismail *et al.*, 1997; Ismail and Shilton, 1998; Chung *et al.*, 2000; Ren *et al.*, 2002; Ismail and Lai, 2003a; Ismail *et al.*, 2003b; Niwa *et al.*, 2004). From the polymer concentration aspect, polymer solution exhibited a significant chain entanglement which played an important role in the formation of membrane morphology and membrane performance. Increasing polymer concentration of casting solution will form a denser and thicker skin layer, resulting in a more selective but less productive asymmetric membranes for gas separation as described by previous researcher (Lai, 2002; Pesek and Koros, 1993). The optimum polymer concentration of casting solution therefore has to be determined in order to achieve defect-free and hyperthin-skinned asymmetric membranes for gas separation.

The selectivity of asymmetric membrane prepared through the phase inversion process is generally controlled by the thin skin structure of the membrane. The formation of skin structure is due to the evaporation induced by suitable gases during membrane fabrication. Therefore, it is expected that evaporating the solvent from the interface before precipitating the polymer could increase the polymer concentration at the top layer so that the formation of the skin structure could be

expedited. The skin structure is generally formed from the increase polymer concentration at the casting solution or air interface at the point of precipitation.

Thus, the combination all of the parameters mentioned above, it is expected that the produced membrane exhibit the best separation performance which will be suitable for gas separation application.

1.2 Problem Statement

The different type of nonsolvent additive (NSA), rheological effect, polymer concentration and evaporation condition during membrane fabrication played an important role in the morphology and separation performances of polymeric membrane. Different type of nonsolvent additive used in the casting solution result in the different morphology and separation performances. Lai *et al.* reported that nonsolvent additive was shown to play an important role in the gas performance of poly (4-methyl-1-pentene) (TPX) membranes. The porosity of the membrane is affected by types of NSA used where by adding the NSA into polymer solutions an increased in the pressure-normalized flux was observed (Lai *et al.*, 1996). High pressure-normalized flux does not exhibit that the membrane is in a good performance. Therefore, high selectivity is needed to develop membrane with hyperthin-skinned and defect-free. Therefore, this studies focus on the development and optimization of the membrane formation process of asymmetric polyethersulfone membrane for gas separation.

1.3 Objectives of the Study

Based on the problem statement described in the previous section, the following are the objectives of this research:

1. Developing new types of polymer solution formulation to fabricate high performance and defect-free asymmetric polyethersulfone membrane for gas separation application.
2. Improving phase inversion conditions so as to provide a platform for enhancing membrane selectivity.
3. Inducing and controlling molecular orientation during membrane fabrication through rheological conditions.
4. Correlating membrane performance with fabrication conditions hence producing high performance and defect-free membrane.

1.4 Scopes of Research

In order to achieve the above mentioned objectives the following scopes were drawn:

1. To develop an optimum casting solution formulation and casting conditions for the development of high performance and defect-free polyethersulfone membrane.
2. Casting solution which develop from various type of nonsolvent additive (NSA) were then cast through a dry/wet phase inversion technique using pneumatically-controlled casting machine. During the membrane fabrication, two variables were studied there are the evaporation time and the shear rate.
3. Characterization of the developed membrane using pure gases N_2 and O_2 as test gases.
4. Morphological studies of the surface layer and cross section of the developed membrane using Scanning Electron Microscopy (SEM).
5. Direct measurement of molecular orientation in asymmetric membranes using Attenuated Total Reflection Fourier Transform Infrared Spectroscopy (FTIR ATR).
