Abstract

In this paper, we present an investigation into using fuzzy methodologies to guide the construction of high quality feasible examination timetabling solutions. The provision of automated solutions to the examination timetabling problem is achieved through a combination of construction and improvement. The enhancement of solutions through the use of techniques such as metaheuristics is, in some cases, dependent on the quality of the solution obtained during the construction process. With a few notable exceptions, recent research has concentrated on the improvement of solutions as opposed to focusing on investigating the 'best' approaches to the construction phase. Addressing this issue, our approach is based on combining multiple criteria in deciding on how the construction phase should proceed. Fuzzy methods were used to combine three single construction heuristics into three different pair wise combinations of heuristics in order to guide the order in which exams were selected to be inserted into the timetable solution. In order to investigate the approach, we compared the performance of the various heuristic approaches with respect to a number of important criteria (overall cost penalty, number of skipped exams, number of iterations of a rescheduling procedure required and computational time) on twelve well-known benchmark problems. We demonstrate that the fuzzy combination of heuristics allows high quality solutions to be constructed. On one of the twelve problems we obtained lower penalty than any previously published constructive method and for all twelve we obtained lower penalty than when any of the single heuristics were used alone. Furthermore, we demonstrate that the fuzzy approach used less backtracking when constructing solutions than any of the single heuristics. We conclude that this novel fuzzy approach is a highly effective method for heuristically constructing solutions and, as such, has particular relevance to realworld situations in which the reliable construction of solutions is more important

than the absolute value of penalty function that might be obtained after lengthy solution improvement.

Key words: examination timetabling, fuzzy methodologies, sequential construction

1 Introduction

Examination Timetabling is a significant administrative issue that arises in academic institutions. Timetabling problems are well studied in the academic literature and are well known to represent difficult problems to solve [1]. In general, the problem is concerned with the goal of allocating a time slot for all exams within a limited number of time slots subject to certain constraints. Basically there are two types of constraints - hard constraints and soft constraints. Hard constraints need to be satisfied under any circumstances, whereas the satisfaction of soft constraints is desirable but not absolutely necessary. Different universities emphasise different sets of constraints that reflect their needs. Burke et al reported a variety of constraints that have been implemented by universities in the United Kingdom [2].

In the literature, there has been a wide investigation of automated timetabling approaches from across the artificial intelligence and operational research communities. Approaches such as Evolutionary Algorithms [2–5], Tabu Search [6–9], Simulated Annealing [10], Constraint Programming [11–13], Case Based Reasoning [14,15] and Fuzzy Methodologies [16,17,14] have been successfully applied to timetabling problems. For more details about the variety of approaches that have been investigated, the interested reader can consult a number of survey and overview articles [1,18–24].

In our previous work [16], we investigated the use of fuzzy techniques to consider two pairs of heuristics simultaneously, by using these combinations of heuristics to order exams based on an assessment of how difficult they are to schedule. This ordering was then used to construct timetable solutions through a sequential constructive algorithm. We demonstrated that certain fuzzy combinations could outperform any single heuristic ordering on the benchmark data sets used.

Encouraged by the findings, we now extend this work in order to explore

all three pair-wise combinations of the same three heuristics. Furthermore, we investigate the effect of combining these multiple heuristics by considering three criteria in the construction phase which reflect the effectiveness of the construction technique. These are the computational time, the number of 'skipped exams', and the number of times a rescheduling procedure is required. As the algorithms include a stochastic element, the experiments were repeated a number of times in order to gain a representative view of the different approaches. These experiments have provided more evidence to support our hypothesis that considering multiple heuristic orderings simultaneously can guide a sequential constructive algorithm towards better solutions. Note that techniques for the iterative improvement of the solutions that are constructed are not covered in this work. However, the method that we present does represent a quick and effective procedure for producing the initial solutions for such approaches.

The rest of this paper is organised as follows. In the following Section, the sequential constructive algorithm and fuzzy approach are explained. The problem descriptions and experimental results are given in Section 5. In Section 6, analysis of the experimental results and discussion are presented. Finally, the conclusions are given in Section 7.

2 Timetable Construction

2.1 The Basic Sequential Constructive Algorithm

The sequential constructive algorithm is amongst the earliest approaches that has been used to tackle the examination timetabling problem in an automated way [25–27]. In this approach, the concept of 'failed first' is implemented. The basic idea is to first schedule the exams that might cause problems if they were to be scheduled later on in the process. By doing so, it would appear to be more likely that we can avoid the assignment of exams to time slots which might later lead to an infeasible solution. An infeasible solution is reached when several exams remain unscheduled because exams placed earlier have invalidated all the potentially valid time slots for the remaining exams.

Essentially, the sequence of exams assigned to the timetable will affect the solution quality. To quote [12]:

"... one important issue is the ordering in which the variables are selected and the ordering in which the values are assigned to each variables. Different orderings affect the efficiency of the search strategies significantly."

2.2 Graph Based Heuristic Orderings

Usually, the unscheduled exams are ordered in a sequence that represents how difficult it is thought likely to be to schedule the exams (most difficult first). One type of ordering strategy that has widely been accepted in the timetabling literature has evolved from the graph colouring problem. The timetabling problem in it simplest form (without soft constraints) can be represented as a graph colouring problem, in which the nodes represent the exams, colours represent the time slots and the edges represent the conflict between exams. The following list describes the three graph colouring based heuristic orderings implemented in this research:

Largest Degree (*LD*) First. Exams are ranked in descending order by the number of exams in conflict — i.e. priority is given to exams with the greatest number of exams in conflict.

Largest Enrollment (*LE*) **First.** Exams are ranked in descending order by the number of students enrolled in each of the exam — i.e. exams with the highest number of students are given the highest priority.

Least Saturation Degree (SD) First. Exams are ranked in increasing order by the number of valid time slots remaining in the timetable for each exam — priority is given to exams with fewer time slots available.

In general, heuristic orderings are divided into two categories: static and dy-namic. Static heuristic orderings are predetermined before the start of the assignment process and their values remain the same throughout the process. For the heuristic orderings described above, LD and LE are categorized as static heuristic orderings. The number of exams in conflict with each exam and the number of students enrolled for each exam only need to be calculated once by analysing the specific problem structure. On the other hand, SD is considered to be a dynamic heuristic ordering because the number of valid time slots available for unscheduled exams may change every time an exam is assigned to a valid time slot; in which case, the unscheduled exams need to be reordered.

2.3 Construction and Improvement

Figure 1 depicts a general framework for finding acceptable solutions to a timetabling problem, in which the construction process is termed 'Phase 1' and the improvement process 'Phase 2'. Normally, in Phase 1, an initial solution is constructed by using the sequential construction algorithm. The sequential constructive algorithm requires the following steps to assign all exams to time slots:

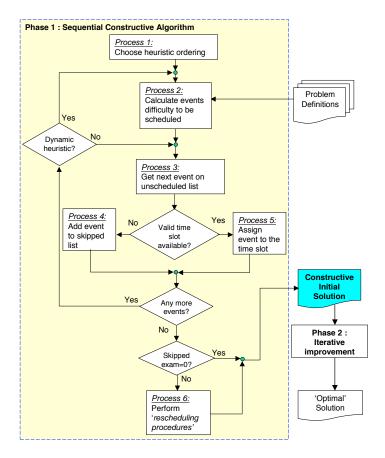

Fig. 1. A general framework for producing timetabling solutions

Process 1 Choose heuristic ordering

In order to determine the sequence in which exams are scheduled to a valid time slot, we have to decide what heuristic ordering is to be employed. Usually, any of the heuristic orderings described earlier can be employed on its own to measure the exams' difficulty to be scheduled. In this paper, we describe an alternative in which two heuristic orderings are considered simultaneously to measure the exams' difficulty. Further details follow.

Process 2 Calculate exams' difficulty to be scheduled

Having chosen a heuristic ordering to be implemented, the calculations of heuristic assessment of difficulty are performed and the exams are ordered in the specified sequence.

Process 3-Process 5 Sequentially assign exams to time slots

For each exam in turn (starting with the most difficult to schedule) the following is carried out. The free time slots are examined in turn to find valid ones, and for each the penalty that would result from placement of the exam in this slot is calculated. After examining each of the time slots, the exam is scheduled into the available slot incurring the least penalty (if two or more slots share the lowest penalty cost, the exam is scheduled into the last such time slot). If no valid time slot is available, the exam is not assigned and is recorded on a 'skipped list'. If a dynamic heuristic is

```
While there exist unscheduled events
   E^* = next unscheduled event that need to be scheduled;
   Find time slots where event E^* can be inserted with minimum number of
    scheduled events need to be removed from the time slot;
   If found more than one time slot with the same number of scheduled events
    need to be removed
       Select a time slot t randomly from the candidate list of time slots;
    While there exist events that conflict with event E^* in time slot t
        Et = \text{next conflicted event in time slot } t;
       If found another time slot with minimum penalty cost to move event Et
           Move event Et to the time slot:
           Bump back event {\it Et} to unscheduled events list;
       End if
    End While
    Insert event E^* to timeslot t;
    Remove event E^* from unscheduled event list;
   If dynamic ordering heuristic is in used
Sort unscheduled events using selected heuristic ordering;
   End if
End While
```

Fig. 2. Pseudo code for the *rescheduling procedure* used when 'skipped' exams are present

being used, the remaining exams' difficulties are updated and the exams are reordered accordingly.

Process 6 Perform a 'rescheduling procedure'

This process is only performed when there is at least one exam that could not be scheduled because no valid time slot was available — i.e there are skipped exam(s) from *Process 3*. The process for scheduling the skipped exams is shown in Figure 2.

These processes continue until all the exams are scheduled, i.e. until a feasible solution is constructed. Although in some approaches infeasible solutions are initially accepted (usually to be later 'corrected' during an iterative improvement phase), only feasible solutions are accepted in our implementation.

In Phase 2, the initial solution is modified in order to improve the solution. The improvements can be implemented by using any meta-heuristic search algorithm such as Genetic Algorithms, Tabu Search, Simulated Annealing [28] or the Great Deluge Algorithm [29] (to name just a few approaches).

In this research, we focus only on constructing a feasible solution. Our main aim was to investigate the implementation of a fuzzy approach in considering multiple heuristic orderings for measuring the difficulty of scheduling exams into time slots. A previous study by Carter [30] has shown that using different heuristic orderings in the constructive algorithm will affect the performance of the construction algorithm. Their study indicated that it is not easy to determine which heuristic ordering is the most appropriate (to construct an initial solution that leads to the best iterative improvement) for any given problem in hand.

3 Combining Heuristic Orderings

3.1 The Need to Combine Ordering Heuristics

As stated in the previous Section, when deciding the order of exams to be placed in a timetable, we are dealing with a decision making problem based on more than one attribute (or factor). The problem lies in deciding which attribute should be emphasized in order to obtain the best decision. Often it is difficult to resolve conflicting attributes. Consider the example shown in Figure 3. In this example, there are 10 exams (e1, e2, e3, e4, e5, e6, e7, e8, e9, e10) with the given LD and LE values. Figure 3(a) shows the 10 exams in an unordered list, Figures 3(b) to (f) show the results of using different heuristic orderings to order the 10 exams. It can be seen that when two different heuristic orderings are used individually, the orderings are completely different (see Figure 3(b) and Figure 3(c)).

It is interesting to note that if both heuristic orderings are used as a pair (e.g. use LD as the main attribute and LE to break any tie, or vice versa — see Figure 3(d)), the ordering is almost the same as that produced when only the main attribute used on its own. This can be observed if we compare Figure 3(b) with Figure 3(d); and Figure 3(c) with Figure 3(e).

The most simple method to handle such multiple attribute decision making is just to multiply the value of each attribute by a weighting factor and summate (i.e. form a simple linear combination) In this example, the formulation is just:

$$weight(e_j) = w_l L D_j + w_e L E_j$$

where j = 1, 2, ...n; n is the number of exams; and w_l and w_e are the weighting factors (any real number) for LD and LE respectively. Using a simple combination to represent the relative importance of both attributes can result in quite a different ordering (see Figure 3(e) where weights $w_l = 0.6$ and $w_e = 0.5$ have been used). In effect, neither the LD nor LE attributes alone control the exam ordering; it is determined by considering both attributes simultaneously. However, the problem then becomes that of needing to search for the appropriate values of w_l and w_e to be used. Johnson implemented the formula above [31] for constructing initial solutions although he actually set the w_l weight to a constant value ($w_l = 1$) while varying the w_e value. The aim of this was simply to produce a range of alternative initial solutions which were then subjected to iterative improvement.

	Unordered Ordered by LD only exams list				y	Ordered by LE only

Fig. 3. Example of examinations ordered by various combinations of heuristics

3.2 The Fuzzy Approach

Heuristic orderings are based on assumptions such as, for example, an exam is more difficult to schedule if it has a 'large' number of other exams in conflict or if it has a 'small' number of valid time slots available. This is dealing with linguistic terms, where no exact values for 'large' and 'small' have been defined. The general framework of fuzzy reasoning facilitates the handling of such uncertainty. Since being first introduced by Zadeh in 1965 [32], fuzzy logic approach has been widely used in variations of real world problem domains. Fuzzy systems are used for representing and employing knowledge that is imprecise, uncertain, or unreliable. Thus, our original hypothesis was that this problem might be one where fuzzy techniques fit well. In essence, fuzzy methodologies allow non-linear combinations of multiple heuristics to be considered.

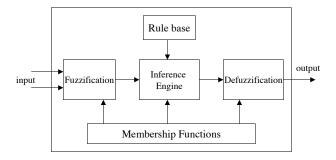

Fig. 4. The components of a fuzzy inference system

Figure 4 shows the interconnected components of a fuzzy inference system. The fuzzification component computes the membership grade for each crisp input variables based on the membership functions defined. The rule base component consists of a set of rules that connect input variables to output variables in 'IF ... THEN ...' form are used to describe the desired system response in terms of linguistic variables (words) rather than mathematical formulae. The 'IF' part of the rule is referred to as the 'antecedent', the 'THEN' part is referred to as the 'consequent'. The number of rules depends on the number of inputs and outputs, and the desired behaviour of the system. Once the rules have been established, such a system can be viewed as a non-linear mapping from inputs to outputs. The inference engine then conducts the fuzzy reasoning process by applying the appropriate fuzzy operators in order to obtain the fuzzy set to be accumulated in the output variable. The defuzzifier transforms the output fuzzy set to crisp output by applying the specific defuzzification method.

More formally, a fuzzy set A of a universe of discourse X (the range over which the variable spans) is characterised by a membership function $\mu_A: X \to [0, 1]$ which associates with each element x of X a number $\mu_A(x)$ in the interval [0, 1], with $\mu_A(x)$ representing the grade of membership of x in A. The precise meaning of the membership grade is not rigidly defined, but is supposed to capture the 'compatibility' of an element to the notion of the set. There are many alternatives for implementing the general fuzzy reasoning methodology. In our implementation, the common Mamdani style fuzzy inference was used with standard Zadeh (min-max) operators. In Mamdani inference [33], rules are of the following form:

$$R_i$$
: if $(x_1 \text{ is } A_{i,1})$ and $(x_2 \text{ is } A_{i,2})$... and $(x_r \text{ is } A_{i,r})$ then $(y \text{ is } C_i)$ for $i = 1, 2, ..., L$

where L is the number of rules, x_j (j = 1, 2, 3, ..., r) are input variables, y is output variable, and A_{ij} and C_i are fuzzy sets that are characterised by membership functions $A_{ij}(x_j)$ and $C_i(y)$, respectively. The final output of a Mamdani system is one or more arbitrarily complex fuzzy sets which (usually) need to be defuzzified. We applied a common form of this process, termed 'centre of gravity defuzzification', as it is based upon the notion of finding the

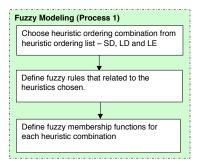

Fig. 5. The steps involved in a fuzzy version of *Process 1* (from Fig. 1) centroid of a planar figure, as given by:

$$\sum_{i} \frac{\mu(x_i) \cdot x_i}{\mu(x_i)}$$

It is not appropriate to present a full description of the functioning of fuzzy systems here; the interested reader is referred to [33] for a simple treatment or [34] for a more complete treatment. An introductory tutorial on fuzzy modelling for the novice can be found in [35].

4 A Fuzzy Model for Timetable Construction

This Section presents the development of our particular fuzzy model. Considering the three single heuristic orderings explained in Section 2.1, there are three alternatives in which two single heuristic orderings can be simultaneously combined. The possible combinations are:

- Largest Degree (LD) and Largest Enrollment (LE), referred to as the Fuzzy $LD+LE\ Model$ in the rest of this paper
- Saturation Degree (SD) and Largest Enrollment (LE), referred to as the Fuzzy SD+LE Model in the rest of this paper
- Saturation Degree (SD) and Largest Degree (LD), referred to as the Fuzzy $SD+LD\ Model$ in the rest of this paper

As mentioned earlier, these three heuristic ordering combinations provide alternative ways for ordering the exams. Therefore, in *Process 1* (see Figure 1), instead of simply choosing any one of the single heuristic orderings to be implemented, we need to modify/improve the process so that the fuzzy approach can be incorporated. Accordingly, the extended version of *Process 1* is shown in Figure 5. It is worth mentioning that fuzzy methodologies are *only* employed in *Process 1*; the other processes in the dotted-box of Figure 1 remain the same.

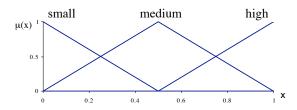

Fig. 6. Illustration of the default membership functions used in each linguistic variable

Fuzzy modeling can be thought of as the task of designing the fuzzy inference system specific to the particular application area. The selection of important parameters for the inference system is crucial, as the overall system behaviour is highly dependent on a large number of factors such as how the membership functions are chosen, the number of rules involved, the fuzzy operators used, and so on. As we are combining two heuristics into a single overall heuristic, a fuzzy system with two inputs and one output is developed. The input variables used are dependent on the heuristic combinations selected. Three pairs of input variables are possible, namely LD and LE, SD and LE, or SD and LD. In any pair of input variables, an output variable called *examweight* is generated. This output variable, examweight represents the overall difficulty of scheduling an exam to a time slot. Each of the input and output variables are associated with three linguistic terms: small, medium and high. Each linguistic term is represented by a fuzzy membership function. Although, in general, any shape of fuzzy membership function is possible, triangular ones are popular due to their relative simplicity. We used triangular membership functions for this reason — a thorough investigation of alternative membership functions would be a major undertaking in its own right and is beyond the scope of the present paper. The basic triangular membership functions implemented are shown in Figure 6.

The range of each input and output variable was defined to be between 0 and 1. This means that the actual input value needed to be transformed into a new value in the range [0,1]. In general, this can be achieved using a simple linear transformation:

$$v' = \frac{(v - min_x)}{(max_x - min_x)}$$

where v is the actual value in the initial range $[min_x, max_x]$. In our case, min_x , was set to zero for each of LD, LE and SD. The maximum values were set by inspection of each problem instance: $max_x(LD)$ was set to the largest number of conflicts found for any exam in the problem instance; $max_x(LE)$ was set to the maximum number of students enrolled to any exam in the problem instance; and $max_x(SD)$ was set to the total number of time slots available in the problem instance.

Table 1 The fuzzy rule set for the $Fuzzy\ LD+LE\ Model$

			LE		VS: very small
		S	M	Н	S: small
	S	VS	S	M	M: medium
LD	M	S	M	Н	H: high
	Н	M	Н	VH	VH: very high

For each heuristic ordering combination, a fuzzy rule set connecting the input variables (any two of LD, LE or SD) to the output variable, examweight was constructed. All three fuzzy rule sets were motivated by the assumption that exams should be placed into a timetable in order of how difficult they are to schedule (most difficult first) and encapsulating the following heuristics:

- (1) If an exam has a large number of other exams in conflict, it is more difficult to schedule than one with fewer exams in conflict (LD).
- (2) If an exam has a large number of students enrolled in it, it is more difficult to schedule than one with fewer students enrolled (LE).
- (3) An exam with a small number of time slots available into which it can be placed is more difficult to schedule than one with more time slots available (SD).

These assumptions were used in order to get a symmetric, balanced set of fuzzy rules for each heuristic ordering combination, to ensure that all possible input values were covered. Note that the interpretation of the SD heuristic (smaller is more difficult) is linguistically opposite to that of LD and LE (larger is more difficult). Thus, care must be taken when considering SD as one of the heuristic orderings in a combination.

The fuzzy rules sets for the Fuzzy LD+LE Model, Fuzzy SD+LE Model and Fuzzy SD+LD Model are shown in Tables 1 to 3, respectively. For simplicity, the fuzzy rules are expressed as a linguistic matrix (see [36]). In such a linguistic matrix, the left-most column and the first row denote the variables involved in the antecedent part of the rules. The second column contains the linguistic terms applicable to the input variable shown in the first column; those in the second row correspond to the input variable shown in the first row. Each entry in the main body of the matrix denotes the linguistic values of the consequent part of a rule.

Note that, in addition to the three basic terms, the *hedge* 'very' was utilised to create two extra terms for the output variable. The 'very' hedge squares the membership grade $\mu(x)$ at each x of the fuzzy set for the term to which it is applied. Thus the membership function of the fuzzy set for 'very small' is obtained by squaring the membership function of the fuzzy set 'small'. For

Table 2 The fuzzy rule set for the Fuzzy $SD+LE\ Model$

			SD		VS: very small

			SD		VS: very small
		S	M	Н	S: small
	S	M	S	VS	M: medium
LD	M	Н	М	S	H: high
	Н	VH	Н	М	VH: very high

instance, the bottom-right entry in Table 1 is read as "IF LD is high AND LE is high THEN examweight is very high". For an illustrative example of how these initial fuzzy models were tuned to best measure the difficulty of scheduling exams to time slots by considering two heuristic orderings simultaneously, the interested reader is referred to our previous paper [16].

5 Computational Experiments

5.1 Problem Description and Cost

The examination timetabling problem data sets which were made publicly available by Carter [30], were used in these experiments. The 12 instances in this benchmark data sets with different characteristics and various levels of complexity are shown in Table 4. For all data sets, it is required to satisfy the defined hard constraint that no student can attend more than one exam at the same time. In addition, the solution must be developed in such a way that it promotes the spreading out of each student's exams so that students have as much time as possible between exams.

The widely used proximity cost function was implemented to measure the timetable quality. Only feasible timetables were accepted and the penalty function was utilized to try to spread out each student's schedule. If two exams scheduled for a particular student were t time slots apart, the weight was set

Table 4
Examination timetabling problem characteristics

YOR-F-83	21	181	941	0.29

to $w_t = 2^{5-t}$ where $t = \{1, 2, 3, 4, 5\}$. The weight was multiplied by the number of students that sit both of the scheduled exams. The average penalty per student was calculated by dividing the total penalty by total number of students. The following formulation was used (adopted from Burke et al [37]):

$$\frac{\sum_{i=1}^{N-1} \sum_{i=1+1}^{N} s_{ij} w_{(p_j - p_i)}}{T},$$

where N is the number of exams, s_{ij} is the number of students enrolled in both exam i and j, p_i is the time slot where exam i is scheduled, p_j is the time slot where exam j is scheduled, T is the total number of students, subject to $1 \le p_j - p_i \le 5$.

5.2 Methods

Due to the randomness in the rescheduling procedure, a different timetable may be constructed each time the algorithm is run. Therefore, in order to determine and compare the performance of the various fuzzy heuristic orderings, repeated runs were performed to generate 30 solutions with each fuzzy multiple heuristic ordering model and each of the single heuristic orderings (LD, LE and SD),

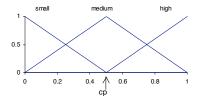

Fig. 7. The fuzzy membership functions were tuned by adjusting the cp parameter

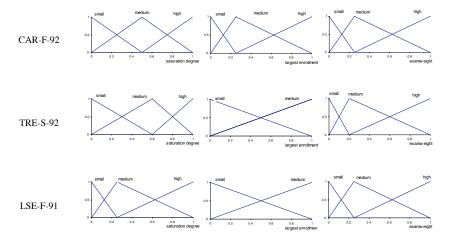

Fig. 8. Example of graphical representation of fuzzy membership functions when implemented in the $Fuzzy SD+LE \ Model$

for each of the 12 data sets described in Section 5.1.

For fuzzy multiple heuristic orderings, the 'best' fuzzy models that had been identified during the membership functions tuning phase were utilised. In the tuning phase, the membership functions were refined by adjusting them until the best possible system performance was achieved. In brief, a parameter cp was used to represent (simultaneously) the right-hand edge of the 'small' term, the middle of the 'medium' term and the left-hand edge of the 'large' term for each of the two inputs and the output variable. The three cp parameters were systematically altered while assessing the performance of the system. For a detailed description of the fuzzy membership function tuning process, please refer to our previous paper [16]. Table 5 shows the values of the cp parameter obtained for each of the fuzzy heuristic ordering combinations for each data set. Graphical representations of the membership functions for some of the 'best' fuzzy models generated when the Fuzzy SD+LE Model was implemented are depicted in Figure 8.

5.3 Experimental Results

Table 6 shows a comparison of the cost penalties obtained based on 30 runs of each data set. The best results among the different heuristic orderings used are

highlighted in bold font. It is evident that, overall, the fuzzy multiple heuristic orderings have outperformed any of the single heuristic orderings in that, for each data set, a fuzzy ordering obtained the best constructed timetable quality. Specifically, the $Fuzzy \ SD+LE \ Model$ obtained 10 best results and the $Fuzzy \ LD+LE \ Model$ and $Fuzzy \ SD+LD \ Model$ each obtained one best result. Amongst the single heuristic orderings, LE is the most effective on these benchmarks in that it obtained 8 best results, followed by SD with 3 best results (HEC-S-92, LSE-F-91 and UTA-S-92) and lastly LD with only one best result (EAR-F-83).

Table 7 shows a comparison of the best result obtained for each data set by the fuzzy approach detailed here with the best results in the literature for other purely constructive methods. That is, methods which have applied iterative techniques to improve solutions have been excluded from the comparison. Clearly, any iterative improvement technique could be applied to the timetable solutions constructed using the fuzzy approach detailed here. It can be seen that for one data set, YOR-F-83, the fuzzy approach obtains the best overall result for any constructive approach. It can also be seen that the result obtained for the STA-F-83 data set is also better than any results previously published, but has recently been beaten by another new approach recently

Table 6
The penalty costs obtained by the different heuristic orderings on each of the 12 benchmark data sets. In each case the best result, the worst result, the average result and the standard deviation obtained over 30 repeated runs are given.

of exams that could not be scheduled after the completion of the initial phase of the constructions process (i.e. after $Process\ 2$ to $Process\ 5$ had been completed). It is simply the number of exams added to the 'skipped list' due to the fact that no valid time slot was available. It can be seen that SD often (7 out of 12 data sets) produced solutions without any skipped exams. This behaviour (most data sets resulting in no skipped exams) is also seen in the fuzzy multiple heuristic orderings that used SD. However, this was not true for two data sets (RYE-F-92 and STA-F-83) when the $Fuzzy\ SD+LD\ Model$ was implemented — i.e. for these two data sets the SD heuristic alone resulted in no skipped exams, but when combined with the LD heuristic in the fuzzy approach some exams were skipped. The number of skipped exams determines whether it is necessary to invoke the $rescheduling\ procedure$ or not. Obviously, it is not necessary to invoke the $rescheduling\ procedure$ if there are no skipped exams.

Table 9 shows a comparison of the number of iterations of the rescheduling procedure required. This table shows the number of iterations of the loop in the rescheduling procedure that were required by each heuristic ordering in order to produce the solutions. As mentioned earlier, the number of skipped exams has an effect on the number of iterations of the rescheduling procedure that are required. If the number of skipped exams is s (where s > 0), then the number of iterations of the rescheduling procedure required is equal to or

Table 8 The number of skipped exams obtained due to the fact that there was no valid time slot available in the first attempt to assign the exam into the time slots — i.e. the number of exams in the skipped list after $Process\ 5$

greater than s. For example, when LD ordering was applied to the YOR-F-83 data set, it caused 5 skipped exams (see column 2 of Table 8). However, on average, 27 iterations of the $rescheduling\ procedure$ were required (see column 2 of Table 9) in order to produce the solutions.

Finally, Table 10 shows a comparison of the computational time required to construct the solutions for each of the heuristic ordering methods for each data set. As might be expected, when dynamic heuristic ordering was used, much longer times were required in order to produce the solutions, because each time around the loop the heuristic needed to be recalculated and the exams reordered. This happened when either a single or a multiple heuristic ordering was implemented.

6 Performance Analysis and Discussions

When constructing solutions for examination timetabling problems, one of the most important aspects that will affect the solution quality is the sequence

in which the events should be selected to be scheduled [12]. Many ordering strategies have been implemented by other researchers. One of the strategies that is widely used is to base various heuristics on graph theory [39]. However, to the best of our knowledge, although there are many such criteria derived from graph theory that could be used as ordering heuristics, only one criterion has been used on its own at any single step of the construction process (except the work of Johnson [31] where the LE and LD heuristic were employed simultaneously simply to construct a number of alternative initial solutions). Another similar approach is one recently published by Burke et al [38] (in press) in which different graph colouring heuristics are applied in sequence to construct solutions for both the examination and course timetabling problem, but only one heuristic is used at any given time.

This paper presents a new heuristic ordering method in which two heuristic

orderings are considered simultaneously using a fuzzy methodology to combine them. The experimental results shown in Table 6 indicates that this new approach is promising. Concentrating on the quality of the solutions, it can be seen in Table 6 that all the best results were obtained when fuzzy multiple heuristic orderings were implemented. This indicates that, in these timetabling problems, determining the difficulty of scheduling exams into time slots by taking into account multiple heuristic orderings simultaneously has resulted in solutions with better quality. The results in Table 7 show that, for the data set *YOR-F-83*, the fuzzy approach obtains the best overall result for any constructive approach.

Nevertheless, there are a few cases in which fuzzy multiple heuristic orderings produced worst solutions compared to specific single heuristic orderings.

For example, for the RYE-F-92, UTE-S-92 and YOR-F-83 data sets the LE heuristic ordering beat the $Fuzzy \ SD+LD \ Model$ (see Table 6), and there are other similar such occurrences. These observations suggest that care must be taken when choosing which heuristic orderings are to be used simultaneously for any given problem instance.

When looking at 'effectiveness' in terms of both solution quality and variation in solution quality, the results indicate that the $Fuzzy\ SD+LE\ Model$ is the most effective heuristic ordering. For all 12 data sets, the 30 multiple runs of this heuristic ordering obtain the same solution quality. Although the $Fuzzy\ SD+LD\ Model$ also managed to obtain the same solution quality for 10 data sets, this fuzzy model only produced one best result out of the 12 data sets. Meanwhile, SD ordering and the $Fuzzy\ LD+LE\ Model$ only managed to produced the same solution for a few of the data sets, while LD ordering only managed to obtain the same solution quality for the STA-F-83 data set.

Since the only stochastic element in our algorithm is when selecting a time slot in the rescheduling procedure, any heuristic ordering that produces an exam ordering which causes no skipped exams will always obtain the same solution in multiple runs. On the other hand, in situations where there are skipped exams (which depends on the problem instance and the heuristic ordering used) these can only be scheduled by reshuffling the already scheduled exams into another time slot, or 'bumping' the scheduled exams back to the unscheduled exam list. It seems obvious that the higher the number of iterations of the rescheduling procedure required, the higher the possibility of obtaining a solution with a different cost penalty. This scenario may explain why the fuzzy membership function tuning process took a long time to finish, particularly for the problem instances that have more than 400 exams. It is assumed that during the fuzzy model tuning process, when a bad fuzzy model is evaluated, its will generate an ordering of the exams which for some reason cannot guide the constructive algorithm towards a good solution. In the case of a bad ordering of exams such as this, many of the exams cannot be scheduled without reshuffling exams that have already been scheduled earlier.

In Table 8, it can be observed that the SD heuristic ordering, the Fuzzy SD+LE Model and the Fuzzy SD+LD Model often produced solutions without invoking the $rescheduling \ procedure$. An interesting point here is that, although the SD heuristic ordering is capable of generating an ordering of exams that required no $rescheduling \ procedure$, when compared against the other single heuristic orderings it only produced 3 best results out of the 12 data sets (see Table 6). In contrast, the exam ordering generated using the $Fuzzy \ SD+LE \ Model$ guides the constructive algorithm without requiring the $rescheduling \ procedure$ and, moreover, it finds solutions which are better than other heuristics in 10 out of the 12 data sets. In addition, although the $Fuzzy \ SD+LE \ Model$ needed to reschedule one exam in the case of HEC-S-92 and UTE-S-92, the solutions

were produced by performing only one iteration of the rescheduling procedure. For the same HEC-S-92 data set, the SD heuristic ordering also produced only one skipped exam but it required 39 iterations, on average, of the rescheduling procedure to produce the solution. When the UTE-S-92 data set is considered, although having only one unscheduled exam, an average of 9 iterations of the rescheduling procedure were required to produce the solution.

Taking these facts into consideration, we may now speculate as to what might be the factors that cause the $Fuzzy\ SD+LE\ Model$ to perform uniformly well across the 12 different data sets. Amongst the single heuristic orderings, LE performed well in 8 out of 12 data sets (see Table 6), while SD often managed to find solutions without skipping an exam (see column 4 of Table 8). It would appear that the fuzzy approach is somehow combining the individual strengths of these two heuristics to improve the overall performance of the search algorithm.

In can be seen that 24 exams are skipped when the single heuristic ordering LD and the Fuzzy SD+LD Model were applied to the STA-F-83 data set (columns 2 and 7 of Table 8). Interestingly, all these skipped exams are then scheduled by performing the rescheduling procedure with the same number of iterations, i.e. 24 (see columns 3 and 8 of Table 9). This means that none of the already scheduled exams needed to be bumped back to the unscheduled list in order to create spaces for the skipped exams. Further investigation has shown that the 24 skipped exams are the same in each case. We examined this closely in order to understand what had caused this curious effect.

In essence, the initial part of the construction process is a greedy algorithm that minimises the penalty of placing each exam, one by one, into the timetable (in the order given by the heuristic determination of difficulty). With the tendency to assign each unscheduled exam into the time slot with least penalty cost, the available time slots are usually occupied at an early stage of the scheduling process. In the case of the STA-F-83 data set with the Fuzzy SD+LD Model, the first 13 exams were assigned to the 13 time slots available, although some of these exams could have been scheduled together in the same time slot — i.e. these 13 did not necessarily clash with each other. In effect, this situation had caused a 'bottleneck', after which no more valid time slots were available. In the next step of the construction process, the rescheduling procedure attempts to schedule each of the skipped exams by considering multiple simultaneous moves of already placed exams in order to obtain feasible solutions. For the STA-F-83 data set, each of the skipped exams could be placed without needing to 'unschedule' ('bump-back') any exams already placed.

Turning now to the computational time, it seems that the $Fuzzy\ LD+LE\ Model$ can be considered to be the best amongst the multiple heuristic orderings we

experimented with since this heuristic always found good quality solutions in relatively low computational time. As seen in Table 6, in terms of solution quality, the Fuzzy LD+LE Model and Fuzzy SD+LE Model were approximately the same. Furthermore, when compared to the various single heuristic orderings, it is apparent that the Fuzzy LD+LE Model heuristic ordering obtained the minimum penalty cost for nine out of 12 data sets. However, in terms of computational time (see Table 10), the Fuzzy SD+LE Model and the Fuzzy SD+LD Model consistently perform worse that the other heuristic orderings.

Considering that the $Fuzzy\ LD+LE\ Model$ combines two single heuristic orderings which are both categorised as static heuristics, it might be expected that this fuzzy model will take more computational time to produce the solution than the two heuristics on which it depends. However, the results presented in Table 10 indicate that in at least 6 out of the 12 cases the $Fuzzy\ LD+LE\ Model$ is actually quicker than the single heuristics, specifically for the CAR-F-92, CAR-S-91, LSE-F-91, RYE-F-92, TRE-S-92, and UTA-S-92 data sets. (It is arguable that is it also quicker for a 7^{th} data set, HEC-S-92, as the $Fuzzy\ LD+LE\ Model$ has a lower average than the other heuristics.) It can be seen that this fuzzy heuristic ordering always obtains the solutions in shorter execution time for the data sets that consist of more than 300 exams, except for KFU-S-93. For the rest of the data sets, the time taken to construct the solution is very reasonable compared to the other single static heuristics.

If we now compare the *longest* time required to produce the solutions among the static heuristic orderings (i.e. those excluding the use of SD) it is evident that the $Fuzzy\ LD+LE\ Model$ always produced the solutions in relatively short time (except for KFU-S-93). This is obvious for the data sets that contain more than 300 exams particularly for CAR-F-92, CAR-S-91 and UTA-S-92 (see Table 10). For example, in the case of the CAR-F-92 data set (looking at the $Worst\ row$), the $Fuzzy\ LD+LE\ Model$ only took approximately 3 seconds, whereas the other heuristics took at least 217 seconds. Although it takes a long time to search for the 'best' fuzzy model, it is important to notice how quickly the 'best' fuzzy model finds the solution compared to these other heuristic orderings.

However, the capability to produce solutions quickly is not achievable when the dynamic heuristic is implemented. As seen in Table 10, the $Fuzzy\ SD+LD$ Model required the longest time in all problem instances as compared to the other heuristics, followed by the $Fuzzy\ SD+LE\ Model$. We believe that most of the time is used to recalculate the number of valid time slots available for the remainder of the unscheduled exams, and not to calculate the fuzzy exam weight. This assumption is based on the observation mentioned earlier, that the $Fuzzy\ LD+LE\ Model$ always obtained the solutions in quick time, meaning that the time taken to calculate exam fuzzy weight must be relatively very small. Moreover, in 10 out of the 12 problem instances, the $Fuzzy\ SD+LE$

Model found the solutions without invoking the rescheduling procedure (and the other two data sets with only one iteration of the rescheduling procedure), which means that no time was spent reshuffling the scheduled exams.

7 Conclusions

The work presented in this paper builds upon and extends our previous work investigating the use of fuzzy techniques in the construction of university examination timetables. In our previous work [16], we carried out a preliminary investigation into the use of fuzzy techniques to combine multiple heuristics used to determine the order in which to place exams into timetables in the construction phase. This previous work considered only a limited combination of heuristics but, nevertheless, highlighted the fact that the fuzzy approach showed promise. In this paper, we have extended this by considering the fuzzy combination of all three pairs of heuristics that are possible from a set of three single heuristics (LD, LE and SD). We have also analysed, in significant depth, the effect of utilising the fuzzy combination of heuristics in the construction process, specifically in its effect on the amount of backtracking required and the associated computational time required. We have evaluated the proposed approach on the 12 Carter benchmark data sets commonly used for comparative purposes in this field of research.

We have shown that the fuzzy combination of SD and LE obtained a good overall performance in terms of low penalty cost on the 12 benchmark data sets. The use of the fuzzy combination of heuristics resulted in lower penalty costs than obtained by the use of any of the heuristics alone, on all 12 data sets. Furthermore, the $Fuzzy SD+LE \ Model$ obtained a penalty cost for one data set (YOR-F-83) that is lower than any other previously published constructive approach. In addition to this, the $Fuzzy SD+LE \ Model$ required less backtracking in the construction process than that observed for any single heuristic used alone. We hence conclude that this novel fuzzy approach is a highly effective method for combining heuristics to be used in the construction of examination timetabling solutions. As the process of constructing feasible solutions to examination timetables in real-world situations (as opposed to these benchmark data sets) is often a significant challenge in its own right [40], the fuzzy approach detailed here could be of great benefit.
