Abstract

Methylene blue (MB) is one of the industrial used organic dye and recalcitrant pollutant which creates a serious water pollution. Among the available techniques, photo degradation using light irradiation is one of the desirable choice to treat waste water. In this regard, we synthesized a binary nanocomposite of magnetite decorated with graphene oxide sheet (Fe3O4@GO) with modification of tetraethyl orthosilicate (TEOS) and 3-Aminopropyl triethoxysilane (APTES) by mechanical stirring method. The prepared nanocomposite was tested as a potential heterogeneous catalyst for degradation of methylene blue (MB) under UV irradiation. The synthesized nanoparticles were characterized by using X-ray diffraction (XRD), Field Emission Scanning Electron Microscopy (FESEM), Fourier transform infrared (FTIR), Thermogravimetric Analysis (TGA), and Energy-dispersive X-ray spectroscopy (EDX) techniques. The characterizations confirm the successful synthesis of the nanocomposite. The photocatalytic activity of the catalysts was gradually enhanced with time intervals. The maximum MB removal efficiency of 70.06 % was achieved over Fe₃O₄@GO composite catalyst, remarkably higher than using pure Fe₃O₄ (57.56 %). The newly developed materials was successfully recovered using an external magnet.

Keywords: Binary nanocomposite, Fe₃O₄@GO, APTES and TEOS, methylene blue (MB)

Abstrak

Metilene biru merupakan salah satu pewarna organik industri dan sukar dihapuskan menyebabkan masalah pencemaran air yang serius. Antara pelbagai teknik yang ada, sinaran fotodegradasi adalah salah satu pilihan yang paling dikehendaki untuk merawat air kumbahan ini. Di sini, kami mensintesis nano komposit binary magnetit baharu yang dihiasi dengan lapisan grafinoksida (Fe₃O₄@GO) dengan pengubahsuaian APTES dan TEOS melalui kaedah pengacauan mekanikal. Nanokomposit yang disediakan telah digunakan sebagai pemangkin heterogeneous yang efektif berpotensi untuk degradasi pencemar metilene biru (MB di bawah sinaran UV. Nanopartikel yang disintesis telah dicirikan menggunakan pembelauan sinar-X (XRD), mikroskopi imbasan electron pancaran medan (FESEM), spektroskopi infra merah jelmaan Fourier (FTIR), analisis termogravimetri (TGA), dan teknik spekro skopisinar –X penyebaran tenaga (EDX). Pencirian-pencirian tersebut mengesahkan sintesis nano komposit yang berjaya. Aktiviti pemangkinan foto nano komposit pemangkin foto tersebut adalah 70.06% iaitu lebih tinggi daripada 57.56% Fe₃O₄ tulen. Pemangkin foto yang baru dibangunkan boleh didapatkan semula dengan jayanya menggunakan sebuah magnet luar.

Kata kunci: Komposite nano Binari, Fe₃O₄@GO, APTES and TEOS, methylene blue (MB)

Full Paper

1.0 INTRODUCTION

Water pollution is one of the main hazards and challenges that human beings are facing today. Dyes are among these organic pollutants, which change the environmental water quality [1]. Dyes wastewater which is discharged from several industries like textiles, printing, food and cosmetics and has developed a key hazard to human and ecosystem due to the toxicity and nonbiodegradability [2, 3]. For the removal of dye from the water, several conventional processes are used, but they have high operating cost, low removal efficiency and slow procedures and at higher concentrations of the organic pollutants in particular, they possess some complications during operation [4]. Photo-degradation is a promising method for the treatment of toxic and bio-resistant pollutants, and this process has some advantages on the other opposing methods. These are: (i) No secondary pollution production, (ii) complete mineralization, (iii) only mild temperature and pressure conditions are necessary and (iv) low cost [5]. Some of the semiconductors, which have been produced and studied as photocatalysts contain ZnO, TiO₂, SrTiO₃, Fe₂O₃, CdS, WO₃, ZnS, FeTiO₃, ZrO₂, V₂O₅, Nb₂O₅, SnO₂ and so on [6, 7]. These photocatalysts demonstrate catalytic activity along with positive better applicability, however, the timely separation of photocatalysts from the purified aqueous solutions sometimes becomes a challenging problem. If the already used catalysts cannot be totally recovered, then the secondary pollution may get activated via the residual photocatalyst powder [8, 9]. What is more, recyclability is similarly a new vital feature for a photocatalyst because it can exceptionally improve the cost-benefit.

To overcome the aforementioned problem magnetite (Fe₃O₄) nanoparticles (NPs) are used as photocatalyst which are eco-friendly nanomaterial, which exhibit characteristics like magnetic separation, easy recovery, and enhancement decent magnetic, electric, catalytic properties and biocompatibility [10]. Fe₃O₄ have large surface to volume ratio and have high surface energies. Redistribution and changing coordination situation of charge and atoms at the surfaces of nanoparticles intensely effects their reactivity. Furthermore, covalently bound surfactants avoid agaregation and increase dispersion stability of nanoparticles by increasing surface charge and electrostatic repulsion or by reducing interfacial energy between particle and solvent [11]. Beside, this coulombic attractions, hvdrophobic interactions, and surfactant concentration affect the adsorbed surfactant mass and layer conformation and hence the ability of a surfactant to stabilize a nanoparticles against aggregation [12]. The average size of the prepared nanoparticles ranging from 50 to 200 nm and high magnetic saturation value (Ms = 48.6 emu/g) and might be used as MRI distinction agents ($r^2 = 36.3 \text{ s}^{-1}$ mM⁻¹) [13]. Moreover, Fe₃O₄ has magnetic moments for an 8-nm dot and 53-, 93-, and 174-nm single clusters of 8.45×10⁻¹⁷, 3.23×10⁻¹⁴, 1.79×10⁻¹³, and 7.13×10⁻¹³ emu, respectively [14]. The superparamagnetic characteristics of Fe₃O₄ tolerate separation under low magnetic fields to allow recycling and reuse. Furthermore, the naked Fe₃O₄ NPs have high chemical activity, and are simply oxidized in air, mostly causing in loss of magnetism and dispersibility [15]. Consequently, if proper surface coating and developing some active protection approaches to possess the stability of magnetic iron oxide NPs is very significant. Practically, it is worthy that in many cases the protecting shells not only stabilizes the magnetic iron oxide NPs, but can also be used for further functionalization [16]. Furthermore, Fe₃O₄ has outstanding conductivity, so it might perform as an electron transfer channel and acceptor, which might destroy the photo-generated carrier recombination. But, because of strong magnetic dipole-dipole attractions between particles, the magnetic Fe₃O₄ NPs tend to aggregate seriously, which greatly limits their application. To overcome this problem of aggregation the researcher start thinking about the hybrid system of Fe₃O₄. So far, a great number of semiconductors such as MnO₂, CdS, SiO₂, TiO₂, and g-C₃N₄, loaded on the surface of Fe₃O₄ have been investigated to design visible-light-driven composite photocatalysts [17, 18]. These hybrid NPs photocatalytic system strategy must fulfil the following necessities: facile preparation and synthesis method, high photocatalytic capacity, can be recycled by external magnetic fields and possess excellent photo decomposition resistance capacity [19].

One more active method for enhancing the performance of hybrid Fe₃O₄ NPs photocatalyst is the use of carbon materials as a composite which shows an active electron transfer reactions. In this consequence, two-dimensional carbon materials such as activated carbon, graphene-oxide (GO), graphene and graphdiyne are used as a carbon additive for the Fe₃O₄ photocatalysts [20, 21]. sheets Moreover, graphene have great consideration for developing nanohybrid materials for photocatalyst due to its excellent electrical, thermal, mechanical properties, and high theoretical surface area of up to 2630 m² g⁻¹. The other main capability of GO is to anchor quest molecules on its basal planes by guest-host interaction [22]. On this regards there are two component nanohybrid systems like WO₃/rGO, GO/g-C₃N₄, TiO₂/rGO and Fe₂O₃/rGO, have been developed to achieve higher photocatalytic performance [23, 24].

The Fe₃O₄ hybrid have other various deficiencies like leaching under acidic conditions, being disposed to autoxidation and toxicity. Moreover, uncovered Fe₃O₄ nanoparticles can easily be oxidized under severe extraction situations and lose their magnetism at long-term use. Thus, shelter of the surface of the nanocomposite can be done to moderate these adverse features [25]. For this reason, Fe₃O₄ are surrounded in a polymeric, hybrid or inorganic matrix. The surface of the Fe₃O₄ NPs can be modified by different functional groups. Among these diverse functional groups, the amino groups have bifunctional nature that could remove cationic and anionic pollutants from aqueous media. At low pH values, the protonated amino groups adsorb anionic pollutant by electrostatic attraction, while at higher pH, amino group is used for the removal of cationic pollutants such as heavy metal ions [26]. Tetraethyl orthosilicate (TEOS) and 3-Aminopropyl triethoxysilane (APTES) are the most commonly used functional groups to produced amino-functionalization of silicabased materials [27, 28]. The use of TEOS round the magnetic NPs increases their stability in solution, avoiding or reducing the formation of agglomerates because of magnetic dipole-magnetic dipole interactions. Moreover, TEOS materials are mostly used for functionalization, because of its availability, cheapness, high stability, biocompatibility and flexibility in surface modification [29]. TEOS also help in the formation of a covalent bond between a molecule attached on the GO surface and that of Fe₃O₄ nanoparticles [30]. APTES can provide a rich NH₂ group on the surface of Fe₃O₄ nanoparticles and form hydrogen bonds with functional group present on the GO surface. Furthermore, APTES is normally used to stabilize Fe₃O₄ nanoparticles and to introduce amine groups for successive chemical functionalization [31, 32]. Based on these characteristics in many studies TEOS and APTES are used for the surface modifications of nanoparticles.

Herein, we report the preparation of Fe₃O₄@GO NPs modified by APTES and TEOS nanoparticles. The photocatalytic activities of the hybrid nanocomposite were assessed via the degradation of MB as a model reaction. It is found that Fe₃O₄@GO sphere nanoparticles show excellent photocatalytic activity for degrading of MB in comparison without catalyst. The high photocatalytic activity was endorsed to the high concentration of oxygen vacancies of GO and the existence of Fe⁺³ions in the core/shell catalyst.

2.0 METHODOLOGY

2.1 Materials

Graphite powder, H_2SO_4 , NaNO₃, NaOH, H_2O_2 (30%), and KMnO₄ were purchased from Sigma-Aldrich (USA). Iron (II) sulphate heptahydrate (FeSO₄·7H₂O, 98%, M.wt = 151.91 g·mol⁻¹), sodium nitrite (NaNO₃, 99%), methylene blue (MB), were purchased from Sigma-Aldrich (Nottingham, UK). Isopropyl alcohol concentrated ammonium aqueous solution (NH₃•H₂O 25 wt %) was purchased from Merck KGaA Germany. Ethanol, (99.9%) was purchased from RCI Labscan. TEOS (98%) was purchased from ACROS, APTES was purchased from New Jersey USA, and Acetone was purchased from RCI Labscan Limited. $BaCl_2$ was purchased from sigma-Adrch. All the chemicals were used without any further purification, and solutions were prepared using distilled water and used for all the preparations.

2.2 Synthesis of Magnetic Fe₃O₄ Nanoparticles

Fe₃O₄ nanoparticles were prepared by dissolving 3.3 g of Fe₃O₄ nanoparticles were prepared by dissolving 3.3 g of Fe₃O₄·7H₂O and 2 g of NaNO₃ in 50 mL of distilled water. After that, 20 mL of NaOH solution (2.5 M) was poured into the mixture as it was heated up to 80°C. The reaction was proceed at 80°C under constant stirring to confirm the complete growth of the nanoparticle crystals. After 30 minutes, the resulting suspension was cooled down to room temperature and washed with distilled water repeatedly to remove unreacted chemicals. The magnetic Fe₃O₄ nanoparticles were separated by using an external magnet and dried in an oven at 60°C overnight before coating.

2.3 Synthesis of GO from Grapite Powder Using Modified Hummers' Method

In brief, GO was prepared by the oxidation of graphite using KMnO₄ as a strong oxidizing agent. 3 g of graphite and 1.5 g of NaNO₃ was mixed well in 69 mL of concentrated H₂SO₄. The mixture was cooled to 0°C using ice bath and stirred for 15 min. Then 9 g of KMnO4 was added slowly into the mixture while maintaining the temperature below 20 °C to prevent overheating and explosion. After stirring for 2 hr the ice bath was replaced by water bath and the mixture was then stirred vigorously for another 30 min at 35 °C. RO water (150 mL) was added and the temperature of the mixture was maintained below 95°C for 15 min of stirring. Finally, the reaction was terminated by addition of RO water (500 mL) and 30% H₂O₂ solution (15 mL) to reduce the residual permanganate and manganese dioxide to colourless soluble manganese sulphate. The resulting mixture was filtered, and then filtered graphene oxide was washed with 5% HCl aqueous solution until sulphate could not be detected by BaCl₂. The GO was then washed by RO water and centrifuged until the supernatant reaches pH 5 to 6. Then the GO solution was ultrasonicated for 1hr and the GO mud was obtain by centrifuging at 4000 rpm for 2 hours to remove large and not fully exfoliated GO. The GO was dry in vacuum oven at 60 °C for 12 hrs. To further purify the GO, the dried GO was dissolved back into large amount of acetone and was stirred vigorously. At last, the GO solution was filtered and the obtained GO cake was dry in vacuum oven again at 60 °C for 6 hrs.

2.4 Preparation of Fe₃O₄@GO Nanospheres

To synthesis magnetic $Fe_3O_4@GO$ nanocomposite, the surface of Fe_3O_4 was first modified with APTES that supplies amide group for more binding graphene oxide by the electrostatic action. 0.1 g of Fe_3O_4 particles were mixed of ethanol (80 mL), deionized water (20 mL) and concentrated ammonia aqueous solution (1.0 mL, 28 wt. %) under ultrasonication, followed by the addition of 67 μ L of TEOS and 67 μ L of APTES. After stirring at 35°C for 3 h, the Fe₃O₄ spheres were functionalized with amino groups (Fe₃O₄@NH₂). The prepared nanocomposite was separated and washed with ethanol and water by an external magnetic field. The binary hybrid of Fe₃O₄@NH₂ were redispersed in the GO aqueous solution (1.0 mg/mL) to synthesize the magnetic graphene (Fe₃O₄@GO) under vigorous stirring at 75°C for 1 h. In direction to eliminate the remaining GO, the achieved Fe₃O₄@GO particles were washed with deionized water for 3 times.

2.5 Instrumentation

A structural details of the samples were studied by Xray diffraction (XRD) (D8 Advance Diffractometer, Bruker, USA) using CueKa radiation (0.154 nm) at 40 kV and 100mA. The field-emission scanning electron microscope (FESEM, JEOLJSM 6380LA) attached with energy dispersive X-ray spectroscopy (EDX) were employed for observing layer formation and elemental analysis. The FTIR spectra of all the compounds were recorded in potassium bromide disks using a Perkin Elmer 2000 system spectrometer in the range 4000-400 cm⁻¹. Thermo gravimetric analysis (TGA) has been carried out (Metler-Toledo) in air (flow rate) 50 mL/min) in the temperature range 30-1000 °C (heating rate) 5 °C/min).

2.6 Photocatalysis Experiments

The photocatalytic activity of the as-prepared composite nanospheres was calculated by photodegradation of MB in aqueous solution under UV. All catalytic reactions were conducted in a 1000 mL radius flask with constant mechanical stirring at room temperature. For the degradation of MB, desired amount of the as-prepared catalysts was added into the 1000 mL aqueous solution containing 20 mg/L MB. The suspension with the photocatalyst but without any H₂O₂ was stirred for 90 min to reach adsorption-desorption equilibrium between the catalysts and MB so that the adsorption in the dark can be discounted. The lamp was turned on while a 0.186 M of H₂O₂ was adding to the mixed solution. During the reaction, 10 mL of sample was withdrawn at each time interval (15 min) and filtered using a syringe filter (Millex PES, 0.22 µm) and the catalysts were collected by magnetic separation. The disappearance of MB was spectrometrically observed as a function of irradiation time using a UV-Vis spectrophotometer at a wavelength 664 nm. The photocatalytic degradation rate and elimination efficiency of MB under UV radiation were calculated by measuring the absorbance of collected solutions by UV-vis spectrophotometer at λ_{max} 664 nm, which is usually determined by

% degradation =
$$\frac{(C_{\circ} - Ce)}{C_{\circ}}$$
 x100

Where, C_0 is the initial concentration of MB and C_e is the concentration of MB at time t during the catalytic reaction respectively.

3.0 RESULTS AND DISCUSSION

3.1 FTIR Analysis

The nanocomposite was studied by FTIR analysis. The main peaks of GO at 3515, 1430, 1630, 1230 and 1080 cm⁻¹ confirm the presence of hydroxyl, carboxyl and epoxide groups on the GO sheets as shown in Figure 1 (A). The transmission infrared spectra of Fe₃O₄@GO of the synthesized products are shown in Figure 1 (B). The strong signal at 576cm⁻¹ is consigned to the Fe-O stretching vibration. In the FT-IR spectrum of the Fe₃O₄@GO, the bands detected in the region of 1400-1600 cm⁻¹ and 1200-1400 cm⁻¹ are the characteristic vibrations of C=N and C–N heterocycles bonds, correspondingly. There is a weak peak at 1640 cm⁻¹ which be similar to the bending vibration of -OH groups that is generally seen in Fe₃O₄ formed by the chemical co-precipitation reaction.

Figure 1 FTIR patterns spectra (A) for GO and (B) for Fe_3O_4@GO explanation

3.2 TGA Analaysis

The thermal stability of the synthesized samples was also confirmed by using TGA analysis as shown in Figure 2. The carbon content of the GO and $GO@Fe_3O_4$ composite was determined by TGA. According to the curve, GO was more thermally unstable than graphite in which it experienced a three step degradation. GO lost 12% weight up to 180 °C. The weight loss could be attributed by the evaporation of adsorbed water and thermal decompositions of oxygen-containing functional

groups like carboxyl, hydroxyl, epoxy, nitrogen dioxide, and ketone. The weight loss rate of GO increased to 34 % with increasing temperature from 180 °C to 220 °C because GO is unstable in high temperature [33]. Furthermore, there is a decrease in the loss rate to attain a maximum value about 44.57 wt. % at about 700 °C, proposing the existence of structural shortcomings in GO produced by strong acid oxidation as shown in TGA curve (A). The weight loss percentage for the Fe₃O₄@GO hybrid was examined from the curve (B), where it showed higher stability than GO in the range 12% up to 220 °C and only 35% than 44.57% at about 870 °C. The maximum weight loss 50.20 % was obtained at about 999.63 °C. From above discussion, it is clear that Fe₃O₄@GO composite is thermally more stable than GO. The combustion of carbon begin around 400 °C, and the weight change was nearly completed at about 999.63 °C. However, the mass that remained constant above 400 °C was consigned to Fe₃O₄@GO [34]. This method can represent the actual Fe₃O₄@GO content which were Fe, C and O in the complex.

Figure 2 TGA explanation (A) for GO and (B) for Fe3O4@GO

3.3 XRD Analysis

The structure of the prepared nanocomposite was also studied by XRD analysis as shown in Figure 3. The characteristic diffraction peaks for Fe₃O₄ ($2\theta = 13.11^{\circ}$, 30°, 35.4°, 43.3°, 53.4°, 57.1° and 62.7°), which can be indexed to their indices (100), (220), (311), (400), (422), and (440), were observed for the synthesized Fe₃O₄ nanoparticles. This result corresponds well to the PDF data (JCPDS file No. 19-0629) which shows that the magnetite diffraction peaks appeared at the same locations. Besides, this result is also in good consistency with the XRD characterization of Fe₃O₄ reported in the former literature [35]. After the modification by APTES, TEOS and GO, only the concentration of the obtained nanocomposite

altered, which have shown that the amount of the GO is too minute to accomplish its crystallinity. Besides that, the crystallinity of Fe_3O_4 was not significantly altered by APTES, TEOS and GO [36].

Figure 3 XRD spectrum (a) for Fe $_3O_4$ (b) GO and (c) Fe $_3O_4@GO$

3.4 FE-SEM Analysis

FE-SEM image analysis is relatively suitable for the investigation of surface morphology and particle size/shape. Figure 4(a) shows the FE-SEM image of sphere shaped Fe₃O₄ particles and the average size of the particles is in the range of 17.2-21.2 nm. These particles are non-aggregated with narrow size distribution. Figure 4(b) shows that the Fe₃O₄@GO particles immobile have morphological the properties of pure Fe₃O₄ except for a slightly larger particle size about 25.5nm to 29.0 nm, which may be due to by the coating of GO on the surface of the magnetic core. Figure 4 (b) shows that the Fe₃O₄ nanoparticles were spread on the basal planes of the graphene. From the figure, one can notice that the graphene sheets were dispersed between the loosely packed Fe₃O₄ and that of a big extent of void spaces formed on the material. Furthermore, the graphene sheets distributed between the Fe₃O₄ can avoid the aggregation of Fe₃O₄ to a certain extent, which can be of great benefit to reactions.

Figure 4 FESEM images for (a) Fe₃O₄ and (b) Fe₃O₄@GO

3.5 EDX Analysis

The synthesized GO and Fe₃O₄@GO particles were also characterized by the energy dispersive X-ray (EDX) spectroscopy by a casting film and the result of Figure 5 (a) show strong peaks of Fe and O. The compositions of the Fe₃O₄ by mass percent are Fe $68.9 \, \%$, O $31.1 \, \%$. The corresponding atomic composition are Fe $55.3 \, \%$, O $15.8 \, \%$ and C $28.9 \, \%$ as depicted in Figure 5 (b) which imply that the nanospheres is mostly consist of Fe, C and O elements. The peak which arise in both Figure 5 (a) and (b) at the position of $2.5 \, \text{eV}$ is attributed to the presence of silica in trace amount due to the modification of Fe₃O₄ by APTES and TEOS but in traces.

Figure 5 EDX survey spectra of Fe_3O_4 spheres (a) and Fe_3O_4@GO (b)

3.6 Photodegradation of MB BY Fe₃O₄ @GO

The photocatalytic activity of the synthesized nanocomposite for degradation of MB under UV-light radiation was studied and the results are shown in Figure 6 (the photolysis of MB (20 mg/L) under the UV light radiation lacking of photocatalyst after 240 min is less than 5%). Hence, the results showed that the photocatalyst plays a predominate role in the dearadation of MB aqueous solution. For comparison, photocatalytic activity was also Fe₃O₄ checked out with and Fe₃O₄@GO nanoparticles. The photocatalytic activity of the Fe₃O₄ toward MB was 57.56 %, this results reveals that the photocatalytic performance of Fe₃O₄ under the UV-light illumination is subsequently slow. At this point, the low degradation efficiency of Fe₃O₄ can be ascribed to its large band gap as well as rapid recombination rate of charge carriers. However, after combination with GO, the photocatalytic activity of the compound photocatalysts are remarkably improved to 70.06%. It is obviously evidenced that photodegradation of MB is higher than Fe₃O₄ catalysed solution. The results implied that the presence of GO plays an important role in enhancing the performance of the Fe₃O₄. poses Graphene-based hybrid photocatalyst numerous advantages over Fe₃O₄ due to the exclusive electronic properties resulting from the sp² hybridized carbon atoms transaction a picosecond ultrafast electron transfer method from the excited semiconductors to the graphene sheet and the controllable size of the semiconductors and reduced aggregation of the graphene sheets promote recover the efficiency of the photocatalysis. Besides, the high transparency of the graphene sheets as of their one- or several-atoms thickness, accelerate the consumption of the exciting light given the conducting and semiconducting properties of graphene, it is probable that photoexcited electrons from Fe₃O₄ are transferred to graphene to hinder electron-hole recombination and to boost oxidative reactivity. Moreover, in incidence of UV irradiation, H₂O₂ plays dynamic role in degradation of MB as it produces two hydroxyl radicals (HO⁻). The HO⁻ are considered exceptionally robust oxidant for the degradation of organic pollutants such as MB [37]. Furthermore, the synergistic interaction between GO

Furthermore, the synergistic interaction between GO and Fe₃O₄ makes the electron transfer easy, which can facilitate the reduction of Fe³⁺ to Fe²⁺as well as generation of HO[•]. Consequently, the combination of H₂O₂ with Fe₃O₄@GO helps in MB degradation. Therefore, the best photocatalytic performance was observed for the Fe₃O₄@GO with the addition of H₂O₂, which was nearly 83.36 % of MB molecules within the UV irradiation for 240 min as shown in Figure 6.

Figure 6 Photocatalytic degradation of MB in the presence of Fe_3O_4, Fe_3O_4@GO hybrids and along with H_2O_2

4.0 CONCLUSION

In this study, the presence of catalyst Fe₃O₄@GO in the photodegradation system has increased the degradation rate of Methylene blue in water. The prepared Fe₃O₄@GO structure was confirmed by characterization of FTIR spectrum, XRD, TGA, FE-SEM and EDX test techniques. The presence of catalyst in the degradation of MB dye was found to be much higher as compared to noncatalysized solution. The modification of Fe₃O₄ by APTES and TEOS proven high thermal stability as described in TGA analysis. The comparison of mono and binary nanocomposite and along with H_2O_2 shown consistency in degradation rate. The high degradation of MB was up to 83.36 % in the presence of H_2O_2 within four hours, which indicates that the system has the potential to be operated in a larger scale.
