“My dearest mum, family, and friends”

This is for all of you

ACKNOWLEDGEMENT

First and foremost, I would like to express my gratitude to my supervisor, Associate Professor Dr. Khairur Rijal Jamaludin and my co-supervisor, Associate Professor Dr. Sufizar Ahmad for giving me the opportunity to work on an interesting topic that inspired passion in me, and for encouraging and advising me throughout the past few years. I have learned a lot from them especially about creative and critical thinking, and self-motivation in researching. Their trust, understanding, and consideration have been invaluable and are highly appreciated. I will strive to carry these qualities with me in the future.

My sincere thanks also goes to Dr. Rosdi and Mr. Nizam from Advanced Materials Research Centre (AMREC), SIRIM Bhd. for their help with the vacuum furnace. Thank you to everyone who helped me with my work. Thank you to all my friends for always filling the work place with fun and happiness, as well as offering great help in every way. It has been such a wonderful journey and great pleasure working with all of you. I also would like to acknowledge support from Malaysian Ministry of Higher Education through the research funding (ERGS-E028) and for the PhD scholarship.

Above all, I would like to give my special thanks to my family: my mom, my husband and my daughters for giving me this life full with love and happiness, for being a driving forces in my life, and for positive support in all direction.

ABSTRACT

The mismatch between elastic modulus of metal implants and bones which is also known as stress shielding, remains an unresolved issue. Porous metals are one of the most effective ways of reducing stiffness mismatches and achieving stable long-term fixation via full bone in-growth. In this work, porous SS316L is produced using the foam replication technique. The samples were each produced with different compositions of SS316L powders and sintered at various sintering parameters including the sintering temperature, sintering time, heating rate and cooling rate. Scanning electron microscopy (SEM) was used to characterise the microstructure while a compression test was used to determine the mechanical properties of the samples. The physical properties including porosity and density were measured according to the Archimedes principles. The biocompatibility test showed that the porous SS316L produced, exhibited no cytotoxicity reactivity. Furthermore, the optimisations of the sintering parameters were performed using the Taguchi method. The optimised porosity of porous SS316L prepared by ball milling method was 85.44% and achieved using sintering time of 60 minutes, sintering temperature of 1200°C, heating rate of 1°C/min, SS316L composition of 60 wt% and cooling rate of 1°C/min. Whereas, for samples prepared by mechanical stirring method, the optimum porosity was 79.46% and occurred for the samples sintered within 60 minutes at 1200°C of sintering temperature, with the cooling and heating rates of 1°C/min and 2°C/min respectively, and prepared with 70 wt% of SS316L composition. In addition, porous SS316L prepared by ball milling method with modulus of elasticity of 0.08 GPa was obtained by using optimum sintering temperature of 1250°C, sintering time of 60 minutes, heating rate of 2°C/min, SS316L composition of 65 wt% and cooling rate of 1°C/min. Whereas, the modulus of elasticity of 0.05 GPa for porous SS316L prepared by mechanical stirring method was obtained by using the optimum cooling rate of 5°C/min, sintering temperature of 1200°C, sintering time of 120 minutes, SS316L composition of 70 wt% and heating rate of 0.5°C/min respectively. Following optimisation, the porous SS316L produced was found to have attractive mechanical and physical properties much like human bone. Notwithstanding, this included interconnected and open porosity in the range of 79.46 to 85.44 %, density in the range of 1.53-1.76 g/cm³, pore size in the range of 247–470 μm, modulus of elasticity in the range of 0.05-0.08 GPa, yield strength in the range of 0.52–0.82 MPa and compression strength in the range of 35.87-64.43 MPa.

ABSTRAK

Perbezaan modulus elastik antara bahan implan dan tulang yang juga dikenali sebagai kesan perisai tegasan merupakan masalah yang masih belum selesai. Logam berbusa adalah salah satu pendekatan yang berkesan untuk menangani masalah ini supaya ia sesuai untuk aplikasi jangka panjang melalui pertumbuhan tulang sepenuhnya. Dalam kajian ini, SS316L berbusa telah dihasilkan dengan menggunakan teknik replikasi Poliurethana (PU) berbusa. Sampel dihasilkan dengan komposisi serbuk SS316L yang berbeza, dan disinter pada pelbagai parameter persinteran termasuk suhu persinteran, masa persinteran, kadar pemanasan dan kadar penyejukan. Pengimbasan mikroskop elektron (SEM) digunakan untuk mengkaji mikrostruktur manakala ujian mampatan dijalankan untuk menentukan sifat-sifat mekanik sampel. Ciri-ciri fizikal iaitu keliangan dan ketumpatan diukur menggunakan prinsip Archimedes. Ujian biokompatibiliti telah menunjukkan bahawa SS316L berbusa yang dihasilkan tidak menunjukkan reaktiviti sitotoksik. Selain itu, pengoptimuman parameter persinteran dilakukan dengan menggunakan kaedah Taguchi. Keliangan optimum untuk SS316L berbusa yang disediakan dengan kaedah pengisaran bebola adalah 85.44% dan diperoleh dengan menggunakan masa persinteran selama 60 minit pada suhu 1200°C dengan kadar pemanasan 1°C/min, disediakan dengan komposisi SS316L sebanyak 60 wt% serta disejukkan dengan kadar penyejukan pada 1°C/min. Manakala untuk sampel yang disediakan dengan kaedah pengadukan mekanikal, keliangan optimum adalah 79.46% dan dicapai setelah disinter selama 60 minit pada suhu 1200°C, dengan kadar penyejukan dan pemanasan masing-masing pada 1°C/min dan 2°C/min, dan disediakan dengan komposisi SS316L sebanyak 70 wt%. Di samping itu, SS316L berbusa yang disediakan dengan kaedah pengisaran bebola dengan modulus keanjalan optimum, 0.08 GPa diperoleh dengan menggunakan suhu persinteran pada 1250°C, masa persinteran selama 60 minit, kadar pemanasan pada 2°C/min, komposisi SS316L sebanyak 65 wt% dan dengan kadar penyejukan pada 1°C/min. Manakala modulus keanjalan optimum, 0.05 GPa untuk SS316L berbusa yang disediakan oleh kaedah pengadukan mekanikal pula diperoleh dengan menggunakan kadar penyejukan optimum pada 5°C/min, suhu persinteran pada 1200°C, masa persinteran selama 120 minit, komposisi SS316L sebanyak 70 wt% dan kadar pemanasan pada 0.5°C/min. Selepas pengoptimuman, SS316L berbusa yang dihasilkan didapati mempunyai sifat mekanikal dan fizikal yang hampir sama dengan tulang manusia. Walau bagaimanapun ini termasuk keliangan terbuka yang saling berkait dalam lingkungan 79.46-85.44%, ketumpatan di antara 1.53 -1.76 g/cm³, saiz liang di antara 247-470 µm, modulus keanjalan di antara 0.05-0.08 GPa, kekuatan alah di antara 0.52-0.82 MPa dan kekuatan mampatan dalam lingkungan 35.87-64.43 MPa.

CHAPTER 1

INTRODUCTION

1.1 Research Background

The mechanical failure of the human body can often be repaired by the surgical implantation of synthetic replacement parts called biological implants. Numerous researches have been conducted over time by the clinicians and engineers to study the physical and mechanical properties of all types of human bones and implants to treat various injuries involving bone replacement. The success of bone replacement with implant depends on many factors such as physical and mechanical properties of the implant material, biocompatibility between a human body with the implant material, patient's health condition and expertise of the surgeon who performs the surgery. At present, the implant material is only able to survive and work well within the human body for about 12 to 15 years. This condition causes re-surgery is needed to monitor the condition of the implant, the patient's health and to replace the implant. Re-surgery and replacement of the implants will involve additional cost to the patient. The cause of the failure of an implant is varies, including the mechanical, chemical, biocompatibility, implant design, surgery, tribology and so forth [1].

Since 1940s, experts from various fields including science, engineering, and medicine have introduced several new processing methods, design concepts, and surgical techniques. Although the 20th century saw many inventions and advances in the development of biomaterials with its own characteristics, however, to date, there is still no implant material that exactly matches the composition, structure, and

property of any part of the human body. In addition, in recent years, nanotechnology, biomimetic, and tissue engineering concepts have rapidly developed and became a new boundary in the development of nanoscale biomaterials [2].

The use of metals as biomedical implants primarily stainless steel, Co-based alloys, Ti and its alloys to replace damaged or failed tissue has begun since the early 1900s. Stainless steel is the first metal implant used successfully in the field of surgery. However, the elastic modulus of stainless steel and Co-Cr alloys is higher than that of the natural bone which is about ten times larger, resulting in some complications of mechanical instability and the structure between the implants and host tissues. The elastic modulus of Ti and its alloy is found to be about five times larger than the natural bone. If a stiffer implant is inserted into hard tissues (eg, Bones), the bones will undergo a reduced mechanical stress which gradually leads to bone absorption. Therefore, this phenomenon is known as a "stress shielding effect" that leads to the death of bone cells [3]. Therefore, low stiffness cellular metals have been produced to overcome this problem.

In the 1970s, the use of porous materials with open pore structure as bone implant has been introduced. Accordingly, this open pore structure promotes the integration of both bones and blood vessels and overcomes the large elastic modulus difference between the bones and the implants. Additionally, porous metals are able to reach similar strength with cancellous bone because of this porous structure. Thus, porous metals have attracted significant attention among medical researchers all over the world due to these unique properties [4].

In order to replace the cancellous bone, there are basically some features that need to be fulfilled by the metal implants which include of having interconnected pores about 30-90% with a pore size in the range of 100-600 μm to provide space for cell migration and new tissue in-growth, and a low Young modulus that similar to the cancellous bone, $<3 \text{ GPa}$ [5].

1.2 Problem Statement

There are two types of orthopedic implants which are temporary implant and permanent implant. Plates and screws are examples of the temporary implant. While for a permanent implant, it usually involved with knees, shoulders, spine, hips, fingers and feet replacements. In the case of a permanent implant, it is very important to ensure that the bonding between the implant material and the living tissue is strong enough and safe. This strong bonding can be achieved through the tissue in-growth within the open and interconnected pores of the implant materials [6]. However, the current metal implant still has some weaknesses. First, the bonding strength is still not high enough and needs to be improved. Second, the large difference of elastic modulus between the bone and implant should be reduced.

Figure 1.1 shows the elastic modulus of most materials that currently used for biomedical applications. From this diagram, it is clearly shows that the elastic modulus of cancellous and cortical bone is very low compared to the elastic modulus of metal implants, especially in the case of stainless steel. This will cause stress shielding to occur on the interface that will affect the long-term stability of the implant [7]. This stress shielding problem still remains as an issue of attention among researchers around the world. In fact, the use of porous materials as implant materials also attracts researchers' interest and attention as a very effective method to reduce excessive stiffness and modulus of elasticity to achieve long-term stability. The elastic modulus of porous metal implants can be modified to match the human bone and thus help prevent the effect of stress shielding on the bones and implants. In addition, porous metal can provide space for bone ingrowth to achieve biological fixation.

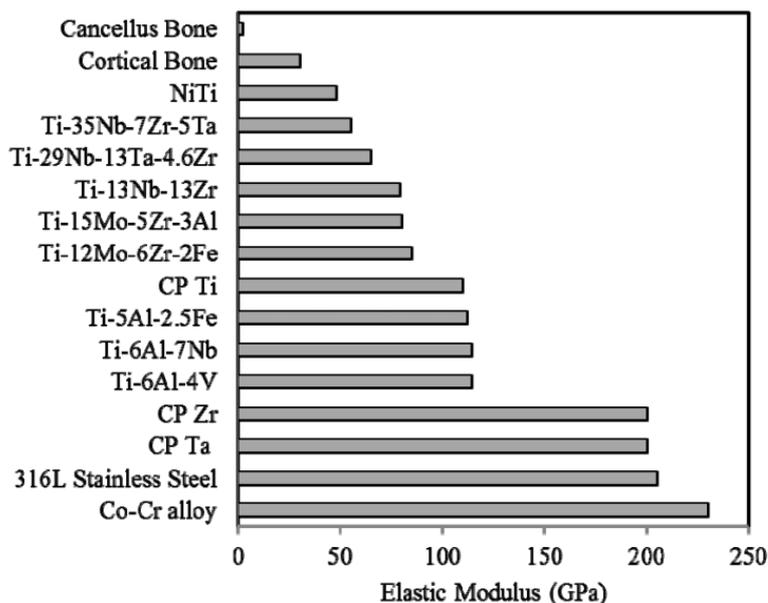

Figure 1.1: Elastic modulus of currently used materials for biomedical application [8]

Nowadays, there are several metallic implants that have been replaced by ceramic and polymer implants due to their superior biocompatibility properties compared to metallic implants. However, for implants that require high strength and durability, the use of metallic implants is very essential. Until now, stainless steel grade 316L, cobalt alloys, pure commercial titanium and Ti-6Al-4V alloys are the most widely used metallic biomaterials for implant devices. These materials possess high corrosion resistance, biocompatibility, and good mechanical properties, especially titanium and titanium alloys [1]. However, titanium and titanium alloys are more expensive than stainless steel and have lower wear resistance than the others. In addition, compared to Ti and Co-Cr alloys, SS316L have the longest history of applications in biomedical implant and have a good workability, fracture toughness, low cost and easy availability [9, 10]. In fact, the successful of stainless steel 316L application as an implant material in human life has been proven for a long time.

Porous materials can be produced through various fabrication method. However, choosing the appropriate manufacturing process is very important since the pore distribution, size, shape and volume porosity of the porous material produced depends on the type of fabrication method used. It is known that, the pore structure of the cancellous bone is open and interconnected. Therefore, fabrication methods that can produce such open and interconnected pore structure need to be identified. Among

all the fabrication methods, foam replication method is one of the methods that is capable of producing a porous structure similar to the cancellous bone and has been widely used for decades [4, 7]. This method initially used to produce porous ceramic materials, but has been used to produce porous metals in 1966. Foam replication is a very economical powder metallurgical method for producing porous materials with open and interconnected pores, and also with a unique combination of properties that is suitable for various applications. In general, this fabrication method involves three main processing steps. The polyurethane (PU) sponge will be immersed and coated with metal slurry first. Then, the polyurethane sponge will be removed thermally and finally, the debinded metal structure will be sintered. Thus, it is possible to fully transform the open and interconnected pores of PU foam into open and interconnected pores of the porous metal. In principle, the fabrication process using this method seems quite simple, but to obtain the pore structure without any defects and with optimum properties, every single processing step needs to be done properly [4, 7]. The using of the appropriate metal composition during the preparation of the metal slurry and the parameters involved during the sintering process will affect the structure and properties of the porous metal produced. To date, there has been limited comprehensive research that studies the parameters involved in each processing step for the fabrication of porous SS316L with open and interconnected pores using foam replication methods especially for applications as biomedical implants. Therefore, this study was conducted to identify the optimum SS316L compositions and sintering parameters which can produce SS316L with porous structure and properties that match the cancellous bone [4, 7].

1.3 Research Objectives

The primary aim of the research is to develop porous SS316L for biomedical applications by using the foam replication method. The objectives of the research are:

- i. To develop porous SS316L by the foam replication method.
- ii. To analyze the physical and mechanical properties of the porous SS316L produced.

- iii. To characterize the microstructure and morphology of porous SS316L produced.
- iv. To evaluate the biocompatibility of porous SS316L.
- v. To optimize the sintering parameters based on robust parameter design.

1.4 Scope of the study

The SS316L slurry was produced by mixing in a planetary ball mill and a mechanical stirrer. Polyurethane foam was used as a template while polyethylene glycol (PEG) and methylcellulose (CMC) were used as a binder. The composition of the SS316L powder was varied from 40 wt% to 70 wt%, and the sintering process was conducted at 1200°C, 1250°C and 1300°C at the different sintering time of 60 minutes, 90 minutes and 120 minutes respectively. The heating rate was also varied from 0.5°C/min, 1°C/min and 2°C/min. These sintering parameters have been optimized by using a robust parameter design, and the Taguchi method which involves reducing the variation in a process by improving the robustness of the control factor to the noise factor. The objective of the method was to produce a high-quality product at low cost to the manufacturer.

The characterization of the SS316L foam produced after sintering has been carried out by using SEM and EDX to investigate the microstructure, pore shape and size, the elements and composition. Also, other physical and mechanical testing carried out included density, porosity, and compression tests. *In-vitro* testing analyzed the biocompatibility of the SS316L foam as implanted material.

1.5 Significance of Research

For the implant applications, stainless steels remain popular because they are readily available, are acquired at a low cost and exhibit excellent fabrication properties.

Although the biocompatibility of 316L stainless steel is lower than CoCrMo and titanium alloys, it is still the most widely material used in a variety of surgical devices and for short-term implants due to cost savings. Porous SS316L which has comparable properties with natural bone can be produced by the foam replication method, and the problems related to stress shielding can be readily overcome or at least minimized. Notably, this porous SS316L implant will be one the best alternative and also beneficial to the multitude of people receiving implants, especially in developing countries to obtain treatment at an affordable cost.

1.6 Thesis Outline

The structure of each chapter for this thesis outlined as follows. Chapter 1 presents the research background, problem statement, objectives of the study, scope of the study, and arrangement of the thesis.

Chapter 2 discusses and explains what constitutes biomedical implants, the specific properties of natural bones, and the applications of porous materials that are used for biomedical implants. This is then followed by an explanation regarding the techniques used for producing porous materials which focus on the foam replication method. The stainless-steel properties, the application of stainless steel as implant materials and the processes applied in the previous works to produce stainless steel foam is also included in this study. The parameters involved during the sintering process are further discussed, and finally, the theory and method for the Taguchi analysis are described.

The explanation for all raw materials and the equipment used in this study are presented in Chapter 3. Additionally, specific information regarding the preparation of the samples and the international standards employed in testing the samples are also discussed. The details of the parameters studied and analyzed by the Taguchi experimental design are also described in this chapter.

The results and discussions of the physical and mechanical properties of porous stainless steel 316L produced by the foam replication method, the microstructural analysis, biocompatibility test and optimization by the Taguchi method are next presented in Chapter 4. Finally, Chapter 5, which presents the results and findings which are summarised along with suggestions for future work.
